December 7, 2022

## Abstract

It has been widely recognized that tropical cyclone (TC) genesis requires favorable large-scale environmental conditions. Based on these linkages, numerous efforts have been made to establish an empirical relationship between seasonal TC activities and large-scale environmental favorabilities in a quantitative way, which lead to conceptual functions such as the TC genesis index. However, due to the limited amount of reliable TC observations and complexity of the climate system, a simple analytic function may not be an accurate portrait of the empirical relation between TCs and their ambiences. In this research, we use convolution neural networks (CNNs) to disentangle this complex relationship. To circumvent the limited amount of seasonal TC observation records, we implement transfer-learning technique to train ensembles of CNNs first on suites of high-resolution climate simulations with realistic seasonal TC activities and large-scale environmental conditions, and then subsequently on the state-of-the-art reanalysis from 1950 to 2019. Our CNNs can remarkably reproduce the historical TC records, and yields significant seasonal prediction skills when the large-scale environmental inputs are provided by operational climate forecasts. Furthermore, by forcing the ensemble CNNs with 20th century reanalysis products and phase 6 of the Coupled Model Intercomparison Project (CMIP6) experiments, we attempted to investigate TC variabilities and their changes in the past and future climates. Specifically, our ensemble CNNs project a decreasing trend of global mean TC activity in the future warming scenario, which is consistent with our dynamic projections using TC-permitting high-resolution coupled climate model.

9

10   **Key points:**

11   • Ensemble convolutional neural networks (CNNs) are trained to emulate seasonal

12     tropical cyclone (TC) activity using large-scale environmental inputs.

13   • The trained CNNs can be utilized to study seasonal TC variabilities, and their changes in

14     the past, current and future climates.

15   • Skillful seasonal TC predictions can be made using CNN based statistical-dynamical

16     hybrid framework.

17

18    **Abstract**

19    It has been widely recognized that tropical cyclone (TC) genesis requires favorable

20    large-scale environmental conditions. Based on these linkages, numerous efforts have been

21    made to establish an empirical relationship between seasonal TC activities and large-scale

22    environmental favorabilities in a quantitative way, which lead to conceptual functions such as

23    the TC genesis index. However, due to the limited amount of reliable TC observations and

24    complexity of the climate system, a simple analytic function may not be an accurate portrait

25    of the empirical relation between TCs and their ambiences. In this research, we use

26    convolution neural networks (CNNs) to disentangle this complex relationship. To circumvent

27    the limited amount of seasonal TC observation records, we implement transfer-learning

28    technique to train ensembles of CNNs first on suites of high-resolution climate simulations

29    with realistic seasonal TC activities and large-scale environmental conditions, and then

30    subsequently on the state-of-the-art reanalysis from 1950 to 2019. Our CNNs can remarkably

31    reproduce the historical TC records, and yields significant seasonal prediction skills when the

32    large-scale environmental inputs are provided by operational climate forecasts. Furthermore,

33    by forcing the ensemble CNNs with 20th century reanalysis products and phase 6 of the

34    Coupled Model Intercomparison Project (CMIP6) experiments, we attempted to investigate

35    TC variabilities and their changes in the past and future climates. Specifically, our ensemble

36    CNNs project a decreasing trend of global mean TC activity in the future warming scenario,

37    which is consistent with our dynamic projections using TC-permitting high-resolution

38    coupled climate model.

39

**Plain Language Summary**

Tropical cyclone (TC) requires favorable large-scale environmental conditions to generate. Pioneer studies suggested that these constructive conditions include but not limit to warm sea surface temperatures (SSTs), sufficient low-level vorticities, mid-level humilities, and weak-to-moderate vertical wind shears. Several follow-up studies have devoted to improving the empirical linkage between number of TC and environmental conditions and developed sets of TC genesis index based on conventional statistical methods. Although these indices can capture climatology of TC spatial distributions and seasonal cycle reasonably well, their performances in representing the interannual TC variability are significantly decreased. Aim to better represent TC interannual variability and long-term trend using large-scale environmental conditions, we trained ensembles of convolution neural networks (CNNs) based on the combination of observations and large sets of high-resolution dynamical climate simulations. The trained CNNs perform significantly well in capturing observed TC interannual-to-multidecadal variability, and are broadly applicable to many areas of seasonal TC activities. Using deep learning technique, this paper introduces a new potential avenue to improve our understanding of TC variability and future changes.

## 1. Introduction

Mounting observational and modeling evidences have suggested that tropical cyclone (TC) genesis requires certain conducive large-scale environmental conditions. Pioneering work of Gray (1968) summarized the geographic distributions and annual cycle climatology of TC genesis, and also trailblazed the potential linkages between TC genesis events and large-scale environmental factors. Gray (1979) proposed Yearly Genesis Parameter (YGP) and elucidated the constructive environmental factors for TC genesis include warm sea surface temperature (SST) and deep oceanic mixed layer, preexisting low-level cyclonic vorticity, moist mid-troposphere, weak vertical wind shear, and weak atmospheric stability. Substantial progresses have been made since then to improve the quantitative linkage between TC genesis and large-scale environmental favorabilities, and other well-known TC genesis indices have been developed (Emanuel and Nolan 2004, Tippett et al. 2011, Bruyère et al. 2012, Wang and Murakami 2020).

These genesis indices are based on the same principal, which assumes that the favorable large-scale environmental conditions to TC genesis are products of dynamical potentials alone or the combination of dynamical and thermal potentials with different formulations. For example, genesis potential index developed by Emanuel and Nolan (2004; hereafter GPI2004) describes a nonlinear multiplication of four major large-scale climate variables in triggering TC genesis, including absolute vorticity at 850 hPa, relative humidity at 600 hPa, vertical wind shear between 850 and 200 hPa, and theoretical TC maximum potential intensity (Bister and Emanuel 1998). Moreover, Emanuel (2010) modified GPI2004 by replacing mid-level relative humidity with the moist entropy deficit and updated the nonlinear multiplication formulation, which has particular importance in relation to issues of climate change. Broadly following Gray (1978), Emanuel and Nolan (2004), and Emanuel (2010), Tippett et al. (2011) later proposed an improved variant of TC genesis index using similar dynamical and thermal variables but with Poisson regression, and highlighted the contributions from low-level absolute vorticity to TC genesis are capped off when they exceed certain thresholds. All aforementioned TC genesis indices employed both dynamical and thermal climate variables

85    in their formulations, but the relative roles of thermal versus dynamical potentials in TC

86    genesis remain elusive. More recently, Wang and Murakami (2020) developed dynamical

87    genesis potential index (hereafter, DGPI) for recognition of TC genesis potentials, which is

88    purely based on the large-scale dynamical factors, and showed improved skills in

89    representing TC genesis variations especially under future warmer climate.

90         Although these empirical TC genesis indices were able to replicate the seasonal cycle

91    and spatial distribution of observed TC genesis over the globe, their skills in representing the

92    TC interannual variability in various ocean basins are degraded and highly basin-dependent

93    (Menkes et al. 2012). For instance, GPI2004 can capture TC interannual variability

94    reasonably well in the North Atlantic and eastern North Pacific, but fail in the western North

95    Pacific (Yu et al. 2018). On the other hand, DGPI can skillfully represent the western North

96    Pacific and North Atlantic TC interannual variability, but it is degraded in the eastern North

97    Pacific (Wang and Murakami 2020). Current TC genesis indices generally have very poor

98    skills in reflecting TC interannual variability in the Indian Ocean. These failures and

99    contrasts in capturing TC interannual variability might be attributable to several reasons. First

100    of all, existing TC genesis indices were derived from the climatological mean values, thus the

101    information of interannual variability were intrinsically not incorporated. Nonetheless, these

102    indices can acceptably reproduce the spatial shift pattern of TC activity modulated by El

103    Niño-Southern Oscillation (ENSO) as in the observations, which is a major driver of TC

104    interannual variability. In addition, the derivation of current TC genesis indices did not

105    consider the spatial variations among different TC-active basins, casting doubt on the

106    applicability of their global usage. For instance, TC genesis mechanisms in the western North

107    Pacific differ from those involved in the North Atlantic due to strong convections over the

108    warm pool area. Murakami and Wang (2010) developed a variant version of GPI2004, by

109    incorporating 500hPa vertical velocity as an additional term into the original formulation,

110    which leads to a significant improvement in the western North Pacific. Similarly, in the more

111    recent paper of Wang and Murakami (2020), they noted that the selected dynamic potential

112    factors through stepwise regression method are basin-dependent, and it is worthwhile to

113   derive variant versions of DGPIs for different ocean basins to optimize the accuracy. As such,

114   using single formulation to represent TC genesis all over the globe would further confound

115   the TC interannual variability.

116       TC genesis indices are also extensively investigated to understand future changes of TC

117   activities, however, the relevance of the thermodynamic factors of TC genesis indices in

118   explaining TC changes under global warming has been questioned. Recent studies by

119   Camargo et al. (2014) and Lee et al. (2020) reported two divergent projections of future TC

120   activity due to the different choices of thermodynamic variables in the TC genesis index.

121   Projections using saturation deficit indicate a decreasing trend, while those using column

122   relative humidity indicate an increasing trend. There is no established theory that can account

123   for this discrepancy, given that both indices yield similar results for the historical period. We

124   hypothesize that an improved representation of TC genesis indices in delineating TC

125   year-to-year variations might facilitate to reduce the uncertainties in TC future projections.

126   Along this line, we attempted to incorporate information of the TC interannual variability

127   into the derivation of new TC genesis index, and use deep learning technique, specifically,

128   convolutional neural network (CNN), to overcome the aforementioned limitations in the

129   current TC genesis indices.

130       In recent years, CNN has been widely utilized in the climate and weather sciences.

131   Research communities use it as a powerful tool to reveal the linkages between

132   three-dimensional predictor fields and the predictand classifications or physical indices (Liu

133   et al. 2016, Chapman et al. 2019, Ham et al. 2019, Bolton and Zanna 2019, Chattopadhyay et

134   al. 2020a, 2020b, Davenport et al. 2021, Weynet al. 2019, 2021, McGuire and Moore 2022).

135   In the context of climate study, pioneering work by Ham et al. (2019) innovatively applied

136   CNNs for multi-year ENSO predictions. In their work, three consecutive months of SST

137   anomalies and ocean heat content anomalies over 0°–360°E, 55°S–60°N were provided to the

138   CNN as the three-dimension predictors, while three-month-averaged Niño3.4 index in the

139   following 23 months were predicted. Inspired by Ham et al. (2019) and previous studies on

140   TC genesis potential indices, in the present study, we aim to develop CNN-based frameworks

141 to emulate basin-integrated seasonal TC activity using the concurrent large-scale

142 environmental factors. Take one step further from classic TC genesis index; our CNN models

143 use seasonal averaged thermal and dynamical large-scale environmental factors as predictors,

144 and the basin-integrated seasonal mean TC metrics, such as number of TC (NTC), number of

145 hurricane (NHU; TCs with lifetime maximum intensity ≥65knots), and Accumulated Cyclone

146 Energy (ACE; Bell et al. 2000), as predictands to depict seasonal TC activities. As such, our

147 framework cannot only emulate TC numbers, but also averaged intensity at a given season.

148 We anticipate that our CNN framework can significantly improve the representation of TC

149 interannual-to-multidecadal variabilities. Of particular interest is to explore the applicability

150 of the new CNN frameworks derived from the present-day climate to the seasonal predictions,

151 reconstructions of past historical records, and future climate projections.

152      The structure of the paper is as follows. In Section 2, the CNN-based TC emulation

153 framework, including the architecture, training and interpretation, are discussed. Applications

154 of CNN framework to seasonal TC prediction, 20th century historical reconstructions, and

155 future projections are presented in Section 3, 4, and 5, respectively. The summary and

156 discussion are given in Section 6.

157

158 **2. CNN model development**

159 2.1 Data for CNN training

160      As discussed earlier in Section 1, large-scale environmental favorabilities on seasonal

161 TC activity are geographic-dependent. As such, we trained various CNNs targeted for seven

162 different TC active basins, including North Atlantic (NAT), eastern North Pacific (ENP),

163 western North Pacific (WNP), North Indian Ocean (NIO), South Indian Ocean (SIO), South

164 Pacific Ocean (SPO), and South Atlantic (SAT), and for three different seasonal mean TC

165 metrics (i.e., NTC, NHU and ACE; total of 21 CNN models). Figure 1a illustrates the

166 boundary of each basin. For the Northern (Southern) Hemisphere basins, we only focus on

167 the June-November (December-May), which is conventionally defined as hurricane season.

168 Following pioneering TC genesis index works, we used 4 environmental factors as the

169   predictors, namely, SST anomalies, saturation deficient (SD; Camargo et al. 2014) anomalies,

170   850 hPa relative vorticity anomalies, and vertical wind shear anomalies between 850 and 200

171   hPa. We also tested the sensitivity of using column-integral relative humidity (CRH; Tippett

172   et al. 2011) anomalies as an alternative humidity environmental factor to replace SD in our

173   CNN model (details in Section 5). Both SD and CRH are calculated following Bretherton et

174   al. (2014). To derive these environmental factors, we firstly interpolate the related prognostic

175   monthly mean data (i.e., temperature, humidity and wind velocities) to 2°×2° resolution grid,

176   then make the diagnostic calculations and seasonal average. Anomalies are finally calculated

177   as the departures from the seasonal mean. These four seasonal averaged predictors are then

178   concatenated as the three-dimensional (i.e., longitude, latitude and variables) inputs to the

179   CNN (Figure 1b). We note that, actual data matrices, rather than images, were implemented

180   as the CNN inputs in our framework. The dimension of the output is one, which depicts the

181   seasonal mean NTC, NHU or ACE, respectively.

182   One big important barrier to implementing deep learning for climate study is the limited

183   sample size of observational data for proper model training (Ham et al. 2019). Due to relative

184   short period of reliable TC observation records, we used transfer-learning technique

185   (Yosinski et al. 2014) to circumvent the limited amount of training datasets and increased the

186   number of training data, in a similar manner as in Ham et al. (2019). We collected suites of

187   high-resolution Community Earth System Model version 1.3 (CESM1.3; ~0.25° resolution

188   for atmosphere/land and ~0.1° resolution for ocean/sea-ice) simulations, including 1850

189   preindustrial control and historical transient climate simulations (Chang et al. 2020), High

190   Resolution Model Intercomparison Project (HighResMIP) 1950s control and historical

191   transient climate simulations (Roberts et al. 2020), and decadal prediction simulations

192   (Yeager et al. 2022), together with Weather Research and Forecast (WRF) based tropical

193   channel model (TCM; 27km) large ensemble hindcast simulations (Fu et al. 2019), to

194   increase the training samples. Both high-resolution CESM1.3 and WRF TCM can faithfully

195   capture the climatology and interannual variability of seasonal mean TC activity and

196   associated large-scale ambient environments (Figure 1a; refer Chang et al. 2020 and Fu et al.

197  2019 for details). We combined these TC-permitting high-resolution climate simulation

198  results with state-of-the-science European Centre for Medium Range Weather Forecasts

199  (ECMWF) Reanalysis v5 (ERA5; Hersbach et al. 2020) and observed TC records from the

200  International Best Tracks Archive for Climate Stewardship (IBTrACS) dataset v04 (Knapp et

201  al. 2010) to optimally train the CNN. It is necessary to point out that we only used the

202  high-resolution CESM1.3 simulations forced with historical condition (climate 1850s/1950s

203  control simulations and transient simulation years before 1979) to train our CNN model,

204  although our transient climate simulations projected the future climate changes up to 2100

205  (Representative Concentration Pathway 8.5 for 2006-2100). We implement our future climate

206  simulations as additional segments for testing processes, aiming to explore the feasibility of

207  applying our CNN model to the future climate projections. Table 1 summarizes the sample

208  size of each datasets utilized in CNN training. We note that simulations conducted by WRF

209  TCM only cover Northern Hemisphere; therefore, 2906 (1506) samples are used to train the

210  CNN models for the Northern (Southern) Hemisphere.

211

212  2.2 CNN architecture

213      We first trained the CNN model on our high-resolution climate simulations from scratch,

214  and the trained weights are then transferred to the new training processes as initial weights to

215  formulate the fine-tuned CNN model using ERA5 reanalysis and IBTrACS TC observations.

216  Figure 1b illustrated the architecture of our CNN model. Input layer has 4 variables

217  containing seasonal mean SST, SD (or CRH), 850 hPa relative vorticity, and vertical wind

218  shear anomalies. Sizes of input layer vary from basin-to-basin (refer Figure 1a for actual

219  sizes). 4 Convolutional processes involve the extraction of local characteristics from the

220  previous layers, with 8, 16, 32 and 32 filters, respectively. Each filter has a kernel size of 3×3.

221  In each convolutional layer, zero padding around the borders of inputs is used to maintain the

222  size before and after applying the filters. Mean-pooling processes reduce the sample size by

223  extracting the mean value from each 2×2 grid with stride of 1. The Scaled Exponential Linear

224  Unit (SELU; Klambauer et al. 2017) is used as the activation function to introduce

225      nonlinearity in the extracted features. The fourth convolutional layer is linked to dropout

226      regularization with dropout probability of 0.2 to reduce the overfitting (Srivastava et al. 2014).

227      The CNN constructs the final prediction through a linear regression output layer, which

228      regresses the desired output onto the intermediate results from the fully connected layer.

229      CNN is trained using a form of stochastic gradient descent, namely, the Adaptive Movement

230      Estimation (Adam) optimization algorithm (Kingma and Ba, 2014), which minimizes the loss

231      function of mean square error (MSE) between the outputs of the CNN and the desired targets.

232      Table 2 lists the key parameters of our CNN model.

233          To minimize the CNN regression output layer model uncertainty due to random weight

234      initialization and stochastic gradient descent, we conducted the ensemble learning. For each

235      targeted basin and TC metric, we independently trained the CNN for 50 times (50-member

236      ensemble) with the same configuration and different initial random weights on the same

237      dataset. Hence, 1050 sets of CNN were trained based on the high-resolution climate model

238      simulations to cover 50-member ensemble of 3 different seasonal mean TC metrics in 7

239      different ocean basins. These trained weights were then used as initial weights to formulate

240      the final CNN model with the training sets confined to the ERA5 reanalysis and IBTrACS

241      observation for the period 1950 to 2019. We note that TC observations are highly uncertain

242      in the pre-satellite era without the support from geostationary satellite imagery (i.e. 1960s)

243      and may significantly underestimate seasonal TC activity (Landsea 2007; Landsea et al. 2008,

244      2014; Vecchi and Knutson 2008, 2010; Vecchi et al. 2021). However, we still include these

245      records in our CNN training processes to enlarge the sample size. We used entire observation

246      data as the training and validation sets (70% for training and 30% for validation, shuffled

247      during each training epoch), and we used leave-one-out cross validation method (LOOCV;

248      Elsner and Jagger 2013) to evaluate the CNN model skills and avoid overfitting due to

249      excessive learning parameters and convolutional layers. LOOCV has been extensively used

250      in the seasonal TC activity training (Li et al. 2013; Murakami et al. 2016). In the LOOCV, we

251      first exclude a single year of observations and predictors; then, we determine the CNN model

252      using the remaining years. Using the model, the seasonal TC metrics for the excluded year

253    are predicted. This is done for 70 years, removing each year's data point successively. In

254    addition, we also cross validate CNN using 20th century reanalysis products, instead of ERA5,

255    focusing on the NAT TC activities before 1950, which were excluded in the training

256    processes. The details are discussed in Section 4.

257        For each of climate model pre-trained CNN, we further deployed 12-member ensemble

258    trainings during the transfer-learning processes on ERA5 and IBTrACS. Although the initial

259    training weights and biases are identical, stochastic Adam optimizer results in deviated CNN

260    regression models due to random choice of mini-batch. In total, for each of TC-active ocean

261    basins and each of seasonal mean TC metrics, we trained ensemble of CNN with

262    600-members. Each model is then used to make a prediction and the actual prediction skill is

263    evaluated by averaging all ensembles, while the ensemble spread indicate the prediction

264    uncertainties.

265

266    2.3 CNN training, validation and interpretation

267        In the rest of this paper, for the sake of clarity, CNN emulated NTC, NHU and ACE

268    were plotted in blue, red and yellow, respectively. Figure 2 illustrates the training and

269    LOOCV skills of seasonal NTC in each TC active ocean basin. It exhibits significant high

270    skills in reproducing NTC variability, in terms of high Pearson correlation coefficient,

271    mean-square skill score (MSSS; Kim et al., 2012; Li et al. 2013) and low root mean square

272    errors (RMSE) over all basins except for NIO. For the NIO, although LOOCV correlation

273    coefficient is still statistically significant at 99% level, it is notably degraded comparing to

274    the trainings and LOOCVs in other TC active basins, which may imply that some nontrivial

275    large-scale environmental factors were not involved in the current CNN predictor variables.

276    In the context of global mean TC activity, the correlation coefficients between observation

277    and ensemble mean CNN training and LOOCV is 0.98, and 0.93, respectively. RMSE

278    between observation and CNN emulated global NTC is 2.27 and 4.95 in training and

279    LOOCV ensemble mean, both of which are significantly smaller than the observed NTC

280    climatology of 79.27 and standard deviation of 12.85. The ensemble spreads of training and

281　LOOCV, which we define as the entire range across 600-member ensemble CNNs and shown

282　as the shadings in Figure 2, are also considerably small among all TC active basins. Similar

283　high skills can also be obtained in the ensemble CNNs that depict seasonal NHU (Figure 3)

284　and ACE (Figure 4) for the period of 1950-2019. All of these promising assessment results

285　are encouraging for proceeding forward with further applications using our CNN framework.

286　　　　Although our trained CNN ensemble frameworks illustrate substantial high skills in

287　reproducing seasonal TC variability in the observational records, an often-cited caveat of

288　machine learning is the challenge of physical interpretability compared to the more

289　conventional method. The potential lack of interpretability has implications for the perceived

290　credibility of the model, where machine learning models may achieve promising results for

291　the wrong reasons (Lapuschkin et al. 2019). To decipher these "black boxes" and gain an

292　insight of what predictor features that predominate CNN's regression output, we further

293　conducted occlusion sensitivity analysis (Zeiler and Fergus 2014).

294　　　　The general concept of our occlusion sensitivity analysis is to check if the trained CNNs

295　can truly identify the physical meaningful spatial patterns in the input layer by systematically

296　occluding different portions of the predictor variables with an occluding mask, and measuring

297　the change degree as a function of the mask position. Intuitively, if a portion of input layer is

298　trivial to the prediction accuracy, and one synthetically mask this portion with "gray patch",

299　one can expect the degradation of prediction skill is also relatively small, and vice versa. As

300　such, we can explore the relative importance of each predictor variables at different

301　geographical locations in determining seasonal TC variability. In practice, for each of four

302　predictor variables during 1950-2019, the patch of 6°×6° (i.e. 3×3 grid) box mask is replaced

303　by its own time-independent climatological values, and new predictions are conducted by the

304　original trained CNN with the altered inputs. Therefore, we obtained the new predictions of

305　seasonal TC variability variability as functions of mask geographical locations and predictor

306　variables. We measure the change in prediction skills as the RMSE between new predictions

307　and original training during 1950-2019, through which we highlight the spatial portion of the

308　predictor variables are the most important to the prediction skills for our trained CNN

309 framework: when that portion of the predictor is occluded to the climatology, the

310 representation of seasonal TC variability will be significantly degraded.

311     Figure 5 shows occlusion sensitivity maps that highlight the relative importance of

312 predictors in emulating the NTC in different ocean basins. Similar occlusion sensitivity maps

313 that decipher the NHU and ACE emulations are illustrated in Supplementary Figure 1 and 2,

314 respectively. As noted earlier in the Section1, it is not surprising to see that the relative

315 importance of each predictor is different among the various TC active basins. Our occlusion

316 sensitivity analysis broadly suggests that large-scale dynamical factors, especially 850hPa

317 vorticity, contribute more than thermal factors in determining NTC and NHU in each basin,

318 and this is physically consistent with the TC dynamic genesis potential index that recently

319 proposed by Wang and Murakami (2021). Take NAT NTC as an example (Figure 5m-p),

320 850hPa vorticity at North Atlantic subtropical gyre and Gulf of Mexico region contributes

321 most to the NAT NTC interannual variability, followed by vertical wind shear in the TC main

322 developed region and Gulf of Mexico, while SST and SD's contributions are relative small.

323 We emphasize that these occlusion sensitivity results does not imply SST are insignificant for

324 regulating seasonal NTC and NHU, because local dynamical factors can be influenced by the

325 remote SST forcing. For example, extensive observational and modeling studies found that

326 Atlantic hurricane seasons are remotely influenced by tropical Pacific SST variability via

327 ENSO teleconnection patterns through both a Walker Circulation type response and an upper

328 tropospheric temperature response (Tang and Neelin, 2004; Smith et al., 2007; Patricola et al.,

329 2016), while Atlantic SST variability can also remotely influence ENP TC activity through a

330 Walker Circulation type response analogous to the ENSO-Atlantic TC teleconnection

331 (Patricola et al., 2017).

332     Interestingly, the relative importance of thermal factors is increased subcutaneously in

333 the CNN ACE emulation. We hypothesized these enhanced thermal contributions may imply

334 local SST and SD are more effective in influencing seasonal mean TC intensity than the TC

335 occurrence. This hypothesis has been partially examined by the Murakami et al. (2018), who

336 found that the hyperactive six major hurricanes during 2017 NAT hurricane season is

337   primarily attributed to the local record high SST anomaly confined to the tropical Atlantic,

338   while the remote influences caused by the moderate La Niña condition in the Pacific played

339   the minor role. More rigorous analysis is planed in the future study. Nonetheless, Occlusion

340   sensitivity analysis provides interpretability to the presented high CNN emulation fidelity,

341   which raises our confidence that our trained CNN frameworks are capable of learning

342   physically plausible mechanism, not only acting just as "black boxes", to account for

343   seasonal TC activities.

344

345   **3. CNN based statistical-dynamical hybrid seasonal TC prediction**

346   With the properly developed CNN framework to emulate seasonal TC activity, in the

347   following sections, we propose a number of different pathways that we anticipate our

348   machine learning model as a starting point to shed light on the future TC studies. We will

349   start with the application of ensemble CNNs in the seasonal TC prediction.

350   Seasonal prediction methods can be broadly categorized into dynamical, statistical, or

351   statistical-dynamical hybrid approach (i.e., dynamical models combined with statistical

352   approaches). As our CNN framework is designed to depict the concurrent empirical

353   relationship between seasonal averaged large-scale environmental factors and TC activities,

354   we can apply the trained ensemble CNNs to the operational seasonal forecast systems that are

355   capable to forecast CNN predictors at various lead times to predict the subsequent seasonal

356   TC activities. In this study, we utilized the National Center for Environmental (NCEP)

357   Prediction Climate Forecast System version 2 (CFSv2; Saha et al., 2014) and ECMWF

358   seasonal forecasting system 5 (SEAS5; Johnson et al., 2019) to drive the proposed CNN

359   based statistical-dynamical hybrid predictions for seasonal TC activity.

360   Both NCEP CFSv2 and ECMWF SEAS5 are atmosphere–ocean–land fully coupled

361   models that aimed for operational seasonal forecasting. But due to the relative coarse

362   resolutions and dynamical model intrinsic biases, CFSv2 and SEAS5 are not capable to

363   faithfully resolve seasonal TC activities. There are 16 CFSv2 runs per day in operations; four

364   out to ~9 months, three out to 3 seasons, and nine out to 45 days. Focusing on our seasonal

365    prediction scope, we only implement those ~9 months long forecasts. CFSv2 hindcast

366    simulations were ran from December 1981 to March 2011, with initial conditions of the 00,

367    06, 12 and 18 UTC cycles for every 5th day starting 00 UTC 1 January of every year (i.e., 292

368    forecasts for every year during 1982-2010). Operational real-time forecasts were available

369    since 1 April 2011, and were operated 4 cycles everyday. For the details of CFSv2 system

370    design, we refer to Saha et al. (2014) for further reading. To obtain the dynamical model

371    forecasted CNN predictors for Northern (Southern) Hemisphere TC seasons of

372    June-November (December-May) seasonal mean, the earliest CFSv2 operational predictions

373    should be initialized at 00 UTC 27 January (July). Here, we defined hybrid forecasts from

374    January (July), February (August), …, May (November) CFSv2 initial conditions as the lead

375    month (LM) 5, 4, …, 1 forecasts for the predictions of Northern (Southern) Hemisphere TC

376    activity in the subsequent TC seasons. To minimize the CFSv2 prediction uncertainties, 20

377    ensemble members (initial conditions from 4 cycles of the last 5 calendar days of

378    January/July) were taken to derive the CNN predictors for the LM5 predictions, and 40

379    ensemble members (initial conditions from 4 cycles of the first 10 calendar days) were used

380    to obtain the predictors for the LM4-LM1 CNN hybrid predictions. For the LM0 hybrid

381    prediction, which we defined as the forecasts initialized in each June (December) 1st, we

382    deployed the dynamical prediction system from ECMWF SEAS5. Different from CFSv2,

383    SEAS5 was initialized on the first day of each month, and ran for 7 months. During the

384    hindcast period of 1981-2016, 25 ensemble forecast members were constructed, and it

385    increased to 51 ensemble members for the operational forecast period from 2017 up to

386    present.

387        For all CFSv2 and SEAS5 dynamical ensemble forecasts, we firstly interpolated the

388    monthly mean prognostic variables (i.e., temperature, humidity and wind velocities) from

389    each of ensemble member to the uniform 2°×2° resolution grid, and then calculated the

390    anomalies based on the 1993-2016 hindcast climatology. These monthly CFSv2 and SEAS5

391    anomalies were further added onto ERA5 1993-2016 climatology to reconstruct the

392    "bias-corrected" predictions, in a similar manner as in Bruyère et al. (2014). We then

393     computed CNN predictor variables based on the bias-corrected monthly mean CFSv2 and

394     SEAS5 predictions, and conducted 6-month seasonal average and ensemble average to obtain

395     the CNN inputs. We utilized these ensemble averaged predicted large-scale environmental

396     factors to drive each of 600-member ensemble CNN emulations, therefore, the uncertainty of

397     our hybrid seasonal TC predictions were determined by the ensemble CNNs, rather than from

398     dynamical model. The actual hybrid prediction skills of 6-month seasonal TC activity depend

399     on both the fidelity of our CNN machine learning model and the CFSv2/SEAS5 dynamical

400     prediction accuracy.

401         Table 3 summarizes the hybrid prediction ensemble mean skills in different TC-active

402     basins. Figures 6, 7 and 8 illustrate the prediction uncertainties of NTC, NHU and ACE,

403     respectively. In general, our hybrid prediction framework yields promising seasonal

404     prediction skills in NAT, ENP, WNP and SPO. For the NAT predictions, the hybrid

405     prediction outperforms persistence predictions and provides skillful forecasts with the

406     correlation coefficient p-values smaller than 0.05 since February initialization. Correlation

407     generally increases with the decrease of prediction lead month with the exception for the June

408     initialization, which might be attributable to the different dynamical model skills in the NAT

409     between CFSv2 and SEAS5. May initialization exhibits the highest skills, with the

410     correlation of the NTC, NHU and ACE of 0.72, 0.69, and 0.67 (Table 3).. For reference, the

411     statistical forecasts issued by Colorado State University (CSU) reported that the prediction

412     correlation coefficients of the NAT NTC, NHU and ACE from their June (April) initialized

413     forecasts during 1982–2021 (1995-2021) are 0.71 (0.31), 0.41 (0.00) and 0.41 (0.02),

414     respectively (data is available from https://tropical.colostate.edu/archive.html#verification).

415     Using hybrid technique with the aid from the Geophysical Fluid Dynamical Laboratory

416     (GFDL) Forecast-Oriented Low Ocean Resolution (FLOR) model, Murakami et al. (2016)

417     reported a high correlation coefficient of 0.75 for the seasonal NAT NTC predictions when

418     their hybrid model was initialized in June, while their targeted forecast season is

419     July-November over the 1980-2014 period.. Comparing to the CSU and GFDL, our hybrid

420     predictions are capable of competing with or even slightly outperforming these pioneering

421    seasonal prediction works in the NAT sector, which demonstrates the feasibility of our hybrid

422    framework in seasonal TC predictions.

423         Similar robust prediction skills can also be obtained in the ENP and WNP. In contrast to

424    the NAT, June initializations exhibit highest prediction skills in terms of correlation and

425    MSSS in these two basins. We highlight the significant high ACE (NHU) correlations of 0.85

426    (0.75), and 0.85 (0.76) for the June initialized predictions in the ENP and WNP (Table 3). To

427    the best of our knowledge, these high fidelities have never been reported in the previous

428    studies yet. Skillful June-November ACE predictions can be obtained since January (Figure

429    8b,c), and skillful NTC and NHU predictions can be made as early as in April (Figure 6b,c

430    and Figure 7b,c). These robust prediction skills make our hybrid prediction model an

431    invaluable tool for North Pacific TC seasonal predictions.

432         However, skillful seasonal predictions in the SPO can only be obtained just ahead of the

433    TC season, December-May (Table 3), and the hybrid framework performs very poorly in the

434    SIO predictions. For the NIO, although hybrid framework fails to produce skillful NTC

435    predictions, it offers skillful NHU prediction in June initialization and ACE predictions at the

436    lead month of 1-4. As we noted earlier, the skillful hybrid seasonal TC predictions presented

437    here are contributed jointly from the dynamical seasonal predictions and the trained ensemble

438    CNN models. In the future studies, we plan to implement multi-model seasonal forecasts

439    from Copernicus Climate Change Service (C3S) Climate Data Store (CDS), including but not

440    limit to, UK Met Office, Météo France, and JMA, and apply the ensemble CNNs in order to

441    see if we are able to obtain higher prediction skills by using the multi-model ensembles.

442

443    **4. Reconstruct historical TC records using CNN and 20th century reanalysis**

444         Another novel application of our CNN framework can be the reconstruction of historical

445    TC activity using the 20th century reanalysis products. Although the IBTrACS NAT TC

446    record can trace back to 1851, before routine airborne reconnaissance in the 1940s and

447    geostationary satellite imagery in 1960s, mounting papers suggested that TC climatology is

448    underestimated before 1970s (Landsea 2007; Vecchi and Knutson 2008, 2011; Vecchi et al.,

449  2021; Emanuel 2010), and numerous efforts have been made to correct for missing TCs.

450  More importantly, TC observations outside the NAT were generally sparse before the

451  satellite era, which impede the robust detection of climate change trend. An innovative

452  approach to remedy this uncertainty is to leverage state-of-the-art 20th century historical

453  reanalysis to either directly identify TC-like structures (Truchelut et al., 2013; Chand et al.

454  2022) from the background flow or use monthly mean large-scale environmental factors for

455  dynamical downscaling (Emanuel 2010, 2021). However, these two methods do not provide

456  consensus on the detection of trends, especially in the NAT basin. In this study, we attempt to

457  utilize the trained ensemble CNN framework to the historical reanalysis and offer a

458  complementary insight of historical seasonal TC activities purely from the perspective of

459  large-scale TC favorable environments.

460      We applied our trained ensemble CNN framework to two historical reanalysis products

461  to derive long-term historical records of TCs globally: NOAA 20th Century Reanalysis

462  Version 3 (1836-2015; Silvinski et al. 2019; hereafter, 20CRv3) and the Coupled ECMWF

463  Reanalysis of the 20th Century (1901-2010; Laloyaux et al. 2018; hereafter, CERA-20C).

464  Using an 80-member ensemble Kalman filter, the 20CRv3 reanalysis assimilates only surface

465  pressure observations, and uses observed monthly mean SST and sea-ice concentration as

466  boundary conditions to create a comprehensive record of the atmospheric circulation.

467  CERA-20C is a 10-member ensemble coupled reanalysis of the twentieth century which

468  assimilates surface pressure and marine wind observations as well as ocean temperature and

469  salinity profiles. Both reanalysis products have been extensively investigated to explore the

470  variability and the trends of the past century extreme weather events and climate. Similar

471  post-processing techniques have been conducted to 20CRv3 and CERA-20C to obtain the

472  CNN predictor variables: we firstly interpolated the monthly mean thermal and dynamical

473  variables to $2°×2°$ resolution grid, then computed the ensemble average and carried out the

474  diagnostic calculations, and finally derived the 6-month seasonal average as the CNN inputs.

475      Figure 9 shows the reconstructed TC records back to 1836 using 20CRv3. In the NAT,

476  Vecchi and Knutson (2008, 2011) and Vecchi et al. (2021) documented the statistical

477  adjustments for the missing tropical cyclones before the satellite era based on the estimations

478  of digitally available ship locations between 1878 and 1965. Combining these statistical

479  adjustments with original IBTrACS observations, we attempt to qualitatively evaluate the

480  fidelity of our historical reconstructions. Our CNN transfer learning is based on the ERA5

481  1950-2019 data; therefore data before 1950 are excluded in the CNN training processes,

482  which acting as the independent segment for the cross verification of our CNN models.

483  Although CNN reconstruction suggested a general decreasing trend during 1878-1950

484  (Figure 9a), which is contrast to the increasing trend in IBTrACS and no trend in Vecchi and

485  Knutson (2008), but is consistent with Chand et al. (2022), the interannual variability can be

486  captured remarkably well. After removing the linear trend, correlation of NTC, NHU and

487  ACE between CNN reconstruction and adjusted observations are 0.66, 0.53 and 0.54,

488  respectively, all of which are significant at 99% confidence level. Although the ensemble

489  spreads are increased comparing to the training period of 1950-2019, spreads before 1949

490  still remain considerably small. These promising cross validations again highlight the fidelity

491  of our CNN framework. It is worthwhile to note that, although our reconstruction approach is

492  very different from Vecchi and Knutson (2008, 2011), Truchelut et al. (2013) and Chand et al.

493  (2022), all our results point to the peak of seasonal TC activity around 1880-1890 (Figure 9a,

494  b; Figure 8a of Truchelut et al. 2013 and Figure 2g of Chand et al. 2022). Furthermore, these

495  independent results clearly suggest that the recent increasing trend of NAT TC activity since

496  1970s is attributed to the multidecadal variability – probably linked to various internal modes

497  of climate variability and reduced aerosol forcing after the 1970s (Vecchi et al. 2021) instead

498  of century scale secular trend (Figure 9a-c). If we assume the fidelity of CNN based historical

499  reconstructions are equally well outside of NAT (unfortunately, TC observations outside the

500  Atlantic were insufficient for validation), our results suggest global NTC experienced

501  insignificant upward trend during 1836-1949, but NHU and ACE were significantly

502  decreased (Figure 9d-f).

503    Supplementary Figure 3 exhibits the historical reconstruction using CERA-20C.

504  Cross-validation with adjusted observations also yield significant high correlation

505 coefficients and small ensemble spreads. In the context of global TC activity trend,

506 CERA-20C indicated insignificant downward trend of NTC and NHU during 1901-1949, but

507 significant downward trend of ACE. Nonetheless, our ensemble CNN framework provides

508 ancillary and independent method to reconstruct historical TC records in the 19th and 20th

509 century. Although our results do not suggest robust decreasing trend of global TC activity as

510 postulated by the recent study (Chand et al. 2022) that used older version (v2c) of NOAA

511 20CR, it does support the findings that the recent increase in NAT TC activity may not be a

512 part of long-term climate trend, but more likely dominated by the internal climate variability

513 and/or aerosol effects (Vecchi and Knutson 2008, 2011; Vecchi et al. 2021).

514

515 **5. Explore future TC activity using CNN and CMIP6 projection**

516       Encouraged by the promising fidelities in emulating TC activities in the past historical

517 and present climate conditions, we further explored the feasibility of applying our trained

518 CNN framework to the TC future climate projections.

519       Although broad consensus has emerged about the increased TC intensity and rainfall

520 rate in the future warmer climates (Patricola and Wehner 2018; Knutson et al. 2020), the

521 uncertainties of future TC frequencies are poorly constrained. For example, vest majority of

522 climate model future projections with TC-permitting horizontal-resolution ($\leq$50km) indicate

523 moderate-to-weak decreasing trend of future TC frequency (IPCC 2013; Zhao et al. 2009,

524 Knutson 2010, 2020; Walsh et al. 2016), but a few others suggest an increased TC frequency

525 (Vecchi et al. 2019). Using the statistical-deterministic method developed by Emanuel et al.

526 (2008), Emanuel et al. (2013) proposed an increasing trend of future TC frequency by

527 downscaling CMIP5 models, while another Poisson regression model (Tippett et al. 2011)

528 based statistical downscaling approach projected two diverging TC frequency climate trends,

529 in which the TC frequency will increase or decrease depending on the selection of the

530 atmosphere moisture variable (CRH or SD) (Camargo et al. 2014; Lee et al. 2020).

531 Specifically, SD-based downscaling leads to a decrease of TC activity, while using CRH

532 results in an increase. The results from the SD choice were consistent with the dynamical

533 simulated TC reduction from Zhao et al. (2009), but those from the CRH choice were in

534 contrast. Given that our CNN is trained devotedly to improve the representation of TC

535 temporal variability, it is intriguing to examine if our CNN framework, which is also trained

536 on present-day climate condition, is applicable to project future TC activities. In particular,

537 we want to test the sensitivity of moisture predictor variables to the sign of projected TC

538 activity trends, consequently, we repeated the CNN training processes as thoroughly

539 introduced in Section 2, but replaced SD with CRH for the sensitivity test. In the rest of this

540 paper, we refer CNN_SD as for the original trained CNN using SD as moisture predictor

541 variable, and CNN_CRH for the newly established framework using CRH. We also note that,

542 the transient climate simulations of 1980-2100 conducted by 3-member ensemble of

543 high-resolution CESM1.3 were excluded from training and validation processes. As the

544 independent segment for cross validation purposes, we made a comprehensive comparison

545 between the CNN emulated TC activities computed from high-resolution CESM1.3

546 large-scale outputs with those directly simulated in 1980-2100.

547     Supplementary Figure 4 exhibits the comparisons between CNN emulated and

548 CESM1.3 direct simulated global NTC, NHU and ACE for the period 1980-2100. Huge

549 discrepancies can be noticed: although CNN_SD and CNN_CRH broadly indicate same sign

550 of change, the CNN emulated NTC increase with time while direct dynamical simulations

551 suggest a significant decreasing trend. Moreover, the ensemble spreads of 600-member

552 ensemble CNN emulation are substantial huge, which is another aspect of significant

553 degradation from the proposed applications in the seasonal prediction and historical

554 reconstruction. These poor performances greatly reduce the potential feasibilities in

555 investigating TC future projections.

556     However, it is noteworthy to point out that transfer-learning technique was employed to

557 both CNN_SD and CNN_CRH, which indicates that CNN_SD and CNN_CRH are strongly

558 constrained by the recent observations. When these observation-constrained CNNs were

559 applied to climate model projections, they may produce biased results due to intrinsic model

560 biases (e.g., SST cold bias, Wang et al. 2014; double ITCZ, Tian et al. 2020) in the climate

561  model projections. To focus on the climate change effects based on the high-resolution

562  CESM1.3 simulations in this study, therefore, we made another sensitivity test that discard

563  transfer-learning technique in the training processing, and use CNNs trained only on the

564  climate model simulations with historical forcing (again, 1980-2100 transient climate

565  simulations were excluded). Figure 10 illustrates similar comparisons but emulated by the

566  non-transfer-learning CNN_SD and CNN_CRH. Notably, we can detect promising

567  improvements: both CNN_SD and CNN_CRH correctly capture the decreasing trend of

568  future TC activity as revealed by the 25-km resolution CESM1.3 simulations, and exhibit

569  robust correlation coefficients. Furthermore, the uncertainty spreads of CNN emulations are

570  significantly reduced comparing to those from the observation-constrained transfer-learned

571  CNNs. Note that, although both CNN_SD and CNN_CRH are trained on the climate

572  historical forcing, where global warming signal is much weaker than those in the mid and late

573  $21^{th}$ century, they still work reasonably-well to predict TC activity changes in the future

574  climate. However, some inconsistencies still exist. For instance, CNN emulated decreasing

575  trends of NTC and NHU are too strong comparing to those directly resolved in the CESM1.3.

576  Nonetheless, the presented results provide positive insights that properly trained CNNs only

577  using present-day climate conditions can still be applicable to investigate the climate change

578  problem.

579      Besides the cross validation using high-resolution CESM simulations, we also applied

580  the non-transfer-learning CNN_SD and CNN_CRH to different 36 CMIP6 models (see

581  Supplementary Table S1 for a list) that participated to the Scenario Model Intercomparison

582  Project (ScenarioMIP), aiming to gain multi-model mean of future TC projections. Figure 11

583  shows the global integrated, and Northern/Southern Hemisphere mean CNN emulated NTC

584  from 36 CMIP6 models. Large-scale environmental conditions for the period of 1950–2015

585  are taken from the historical simulations, and those for the periods from 2015 to 2100 are

586  from future climate simulations under shared socio-economic pathway 5-8.5 (SSP585)

587  scenario. NHU and ACE emulation are illustrated in Figure 12, and 13, respectively.

588  Supplementary 5 and 6 further compare the CNN emulations in each individual TC-active

589  basin. Consistent with many previous studies based on the dynamical model proejctions

590  (Knutson et al. 2015, 2020; Walsh et al. 2016; Sugi et al. 2017; Yoshida et al. 2017), our

591  CNN emulation frameworks also indicate a decrease of seasonal TC activity in the future

592  warmer climate, either using SD or CRH as moisture predictor variable. Specifically, using

593  CNN_SD (CNN_CRH), 35 (36) of total 36 CMIP6 models project decreasing of global mean

594  NTC, which is primarily driven by the significant reduction of NTC in the Southern

595  Hemisphere (Figure 11). Pinpoint to each basin, both CNN_SD and CNN_CRH emulated

596  robust NTC decrease in the SIO (Supplementary Figure S5), as also seen in CMIP5 and

597  HighResMIP studies (Tory et al., 2013; Bell et al., 2019; Roberts et al., 2020). In addition,

598  NTC will be declined in the WNP and SPO, but increased in the NIO. No significant change

599  is projected in the ENP, but NAT yields a mixed projection: increase of NTC up to 2050s, but

600  decrease afterwards. We will explore the plausible physical mechanism for this unusual NAT

601  NTC projection in the future study.

602  Our CNN framework project weaker decrease trends of the global integrated NHU and

603  ACE (Figure 12 and 13). Majority of CMIP6 models project slight increases of NHU and

604  ACE in the Northern Hemisphere, which compensate the substantial decrease trends in the

605  Southern Hemisphere. It is intriguing to note that, although our CNN framework is purely

606  statistical based and the NTC are trained independently from the NHU or ACE, it can still

607  capture the increasing trend of intense TC fraction (Supplementary Figure 6), which is a

608  general consensus emerged from the TC-permitting climate model simulations (Knutson et

609  al., 2020).

610

611  **6. Conclusions and discussions**

612  The overarching goal of this study is to extend the pioneer works of TC genesis index,

613  and to use machine learning technique to better reveal the empirical linkage between

614  large-scale environmental conditions and temporal TC variability. Leveraging large suites of

615  TC-permitting high-resolution climate model simulations and reanalysis products, we trained

616  ensemble of CNNs that yield high fidelity in capturing observed TC

617  interannual-to-multidecadal variability. Using occlusion sensitivity analysis, we confirm that

618  physical plausible mechanisms about TC environmental favorability are properly

619  implemented in the trained CNN framework. We further demonstrate that this CNN

620  framework can be applicable to many aspects of TC-climate studies. In particular, our

621  preliminary applications highlight:

622  Using large-scale CNN predictors forecasted by the operational NCEP CFSv2, the CNN

623  based statistical-dynamical hybrid model can make skillful NAT (WNP and ENP) predictions

624  in early February (late January). In particular, correlation coefficients of the predicted and

625  observed ENP and WNP ACE reach to 0.85 when the hybrid prediction is initialized in June,

626  just at the beginning of conventionally defined hurricane season.

627  By applying CNNs to the NOAA 20CRv3 and ECMWF CERA20C reanalysis products,

628  we found that the recent increase in NAT TC activity since 1970s may not be a part of

629  long-term climate trend, but more likely dominated by the internal climate variability and/or

630  aerosol effects, which agrees with the arguments from previous studies that using entirely

631  different methods (Vecchi and Knutson 2008, 2011; Vecchi et al., 2021; Chand et al., 2022).

632  The observation-constrained (transfer-learning-employed) CNNs illustrate big biases in

633  future climate projections, presumably attribute to the "out-of-sample" error. However, if we

634  discard transfer-learning technique and train CNN entirely on climate model simulations

635  forced by the climate historical condition, our CNN frameworks can promisingly capture the

636  decreasing trend of future TC activity, which is consistent with our direct high-resolution

637  CESM1.3 projections in TC-permitting 25-km resolution. In addition, this projection is

638  independent to the choice of CNN moisture predictor variables. We further applied these

639  non-transfer-learning CNNs to 36 CMIP6 models, and found a robust decrease of global TC

640  activity in the future climate, as documented by the recent TC and climate change assessment

641  (Knutson et al., 2020).

642  In addition to these promising applications, one particularly intriguing property of CNNs

643  is their extreme computational efficiency. Once the CNN predictors are properly computed,

644  the computational cost of CNN prediction is negligible. Our CNN approach is

complementary to earlier TC genesis index studies. We suggest that machine learning approaches, especially deep learning models, may provide a new avenue to improve our understanding of TC variability and future changes. In the future, it would be desirable to train deep learning models on multiple climate model large-ensemble simulations that are able to faithfully reproduce seasonal TC activities, for example, GFDL Seamless System for Prediction and Earth System Research (SPEAR, Delworth et al., 2020) or MRI-AGCM3.2 "Database for Policy Decision-Making for Future Climate Change" (d4PDF; Mizuta et al., 2017), in order to test the sensitivity of CNN seasonal TC activity emulations on the training sets.

**Open Research**

The data used in this manuscript are available from the following sources: ECMWF ERA5 (https://cds.climate.copernicus.eu/cdsapp#!/dataset/reanalysis-era5-single-levels-monthly-means), SEAS5 (https://cds.climate.copernicus.eu/cdsapp#!/dataset/seasonal-monthly-single-levels), CERA20C (https://apps.ecmwf.int/datasets/data/cera20c/levtype=sfc/type=an/), NCEP CFSv2 (https://www.ncei.noaa.gov/thredds/model/cfs.html), NOAA 20CRv3 (https://psl.noaa.gov/data/gridded/data.20thC_ReanV3.html), CMIP6 models (https://esgf-node.llnl.gov/search/cmip6/), IBTrACS (https://www.ncdc.noaa.gov/ibtracs/index.php?name=ib-v4-access). High-resolution CESM1.3 simulations are available at https://ihesp.github.io/archive. As part of this paper, we will also release the trained ensemble CNNs for seasonal TC activity to allow future studies once the manuscript is accepted for peer-reviewed publication.

Table 1: The datasets for training the deep CNN model

| | Datasets | Sample size | Reference |
|---|---|---|---|
| 1 | CESM1.3 1850 pre-industrial control simulation | Year 0338-0519 (total: 182) | Chang et al. (2021) |
| 2 | CESM1.3 1850-2100 transient climate simulation | Year 1877-1979 and 2-ensemble 1920-1979 (total: 223) | |
| 3 | CESM1.3 HighResMIP 1950s control simulation | Year 051-151 (total: 101) | Roberts et al. (2021) |
| 4 | CESM1.3 HighResMIP 1950-2100 historical transient climate simulation | Year 1950-1979 (total: 30) | |
| 5 | CESM1.3 decadal prediction | 10-member ensemble 5-year predictions initialized in every other year from 1982 to 2016 (total: 900) | Yeager et al. (2022) |
| 6 | WRF Tropical Channel Model seasonal hindcast simulation | 35-member ensemble 1979-2018 (total: 1400) | Fu et al. (2019) |
| 7 | ERA5 and IBTrACS | 1950-2019 (total: 70) | Hersbach et al. (2020) and Knapp et al. (2010) |
| | Total: 2906 (1506) for Northern (Southern) Hemisphere basins | | |

Table 2: Detail of CNN architecture and the optimization parameters.

| | |
|---|---|
| Number of convolution layers | 4 |
| Number of filters for each convolution layers | 8, 16, 32, 32 |
| The dimensions of the convolutional filter | $3\times3, 3\times3, 3\times3, 3\times3$ |
| Activation function for each convolutional filter | SELU, SELU,SELU,SELU |
| Mean pooling kernel size | $2\times2$ |
| Stride for mean pooling | 2 |
| Output size | 1 |
| Loss function | Mean square error |
| Optimizer | Adam |
| Max training epochs | 100 |

| Mini batch size for training | 500(climate model)/20(observation fine-tuning) |
|---|---|
| Initial learning rate | 0.001 |

870

871

Table 3. Pearson correlation coefficients between ensemble mean CNN based statistical-dynamical hybrid predictions and observed TC activity with various forecast lead month (LM). Italic bold face highlights statistical significance of the correlations at the 95% level based on two-tailed Student's t-test. The mean-square skill scores (MSSSs; Li et al. 2013; Murakami et al. 2016) are listed in the parenthesis just after correlation coefficients. The MSSS is a metric for the skill comparison of the model and climatology-based forecasts, with higher values indicating a good prediction model. We define forecasts from June (December), May (November) . . . , January (July) initial conditions as the LM 0, 1, . . . , 5 forecasts for the predictions of TC activity in the subsequent season in the Northern (Southern) Hemisphere. We use NCEP CFSv2 (1982-2020) and ECMWF SEAS5 (1993-2020) for LM1-5 and LM0 hybrid predictions, respectively.

883

885
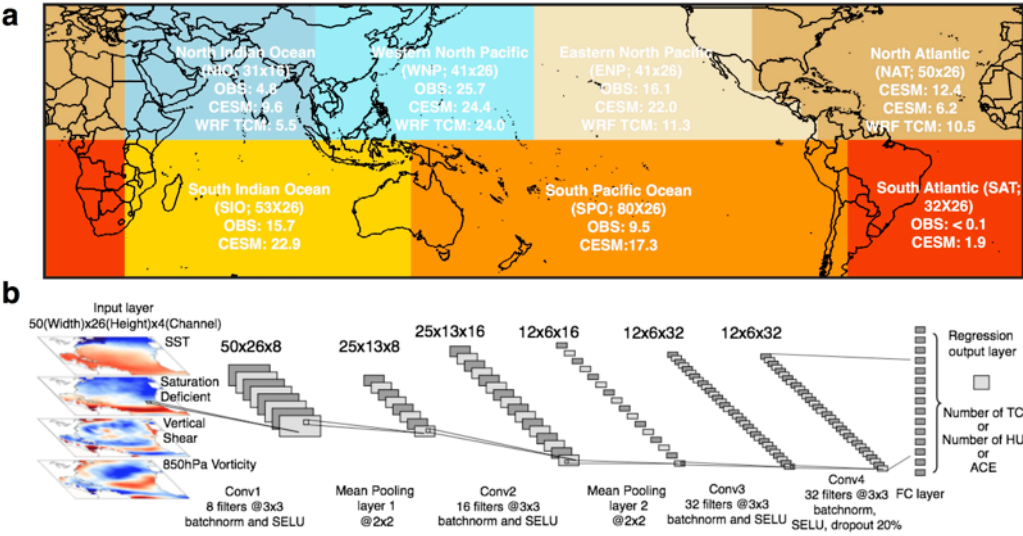

886 Figure 1: (a) Illustration of TC active ocean basin boundaries, including North Atlantic
887 (NAT), eastern North Pacific (ENP), western North Pacific (WNP), north Indian Ocean
888 (NIO), south Indian Ocean (SIO), south Pacific Ocean (SPO) and south Atlantic (SAT). The
889 number in each TC basin shows the annual mean TC member in observation (OBS),
890 high-resolution CESM and WRF tropical channel model (TCM) simulation results, and
891 horizontal dimensions of input layer. (b) Architecture of the CNNs for emulating seasonal TC
892 activity. The CNN model consists of one input layer (predictor; taking NAT as an example),
893 four convolutional (Conv) layers, two mean pooling layers, one fully connected (FC) layer,
894 and one output layer (the predictant). The variables of the input layer contain the anomalies
895 of SST (unit: K), saturation deficit (unit: mm), 200-850 hPa vertical wind shear (unit: m/s),
896 and 850hPa relative vorticity ($10^{-5}$ 1/s) averaged over June-November (December-May) for
897 Northern (Southern) Hemisphere ocean basins. The input variables are interpolated to 2°×2°
898 resolution grid, and the actual size of input layer varies with different ocean basins. The
899 seasonal mean number of TC (NTC), number of hurricane (NHU), or Accumulated Cyclone
900 Energy (ACE) is output (i.e. predictand).

901
902
903
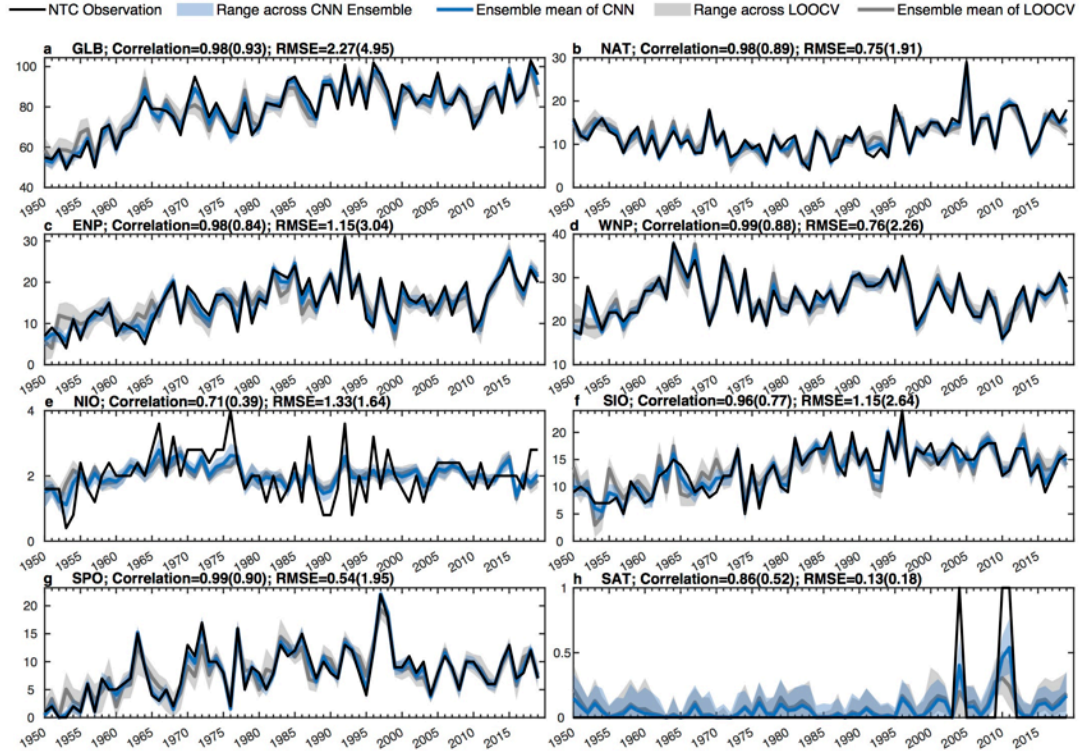

Figure 2: Time-series of seasonal mean number of TC (NTC) for (a) global (defined as the sum of individual ocean basins), (b) NAT, (c) ENP, (d), WNP, (e) NIO, (f) SIO, (g) SPO and (h) SAT. Observed NTC is shown in black line. Ensemble mean CNN emulated and LOOCV results are shown in blue and grey lines, respectively. Ranges across CNN ensembles are shown in shadings. Numbers shown in each panel denote the Pearson correlation coefficients and root mean square errors (RMSE) between observation and CNN model results. Leave-one-out cross validation (LOOCV) results are listed in the parentheses.
913
914 Figure 3: Similar as to Figure 2, but for seasonal mean number of hurricane (NHU; lifetime
915 maximum wind speed ≥33m/s).

916
917

918
919 Figure 4: Similar as to Figure 2, but for seasonal mean accumulated cyclone energy (ACE).
920
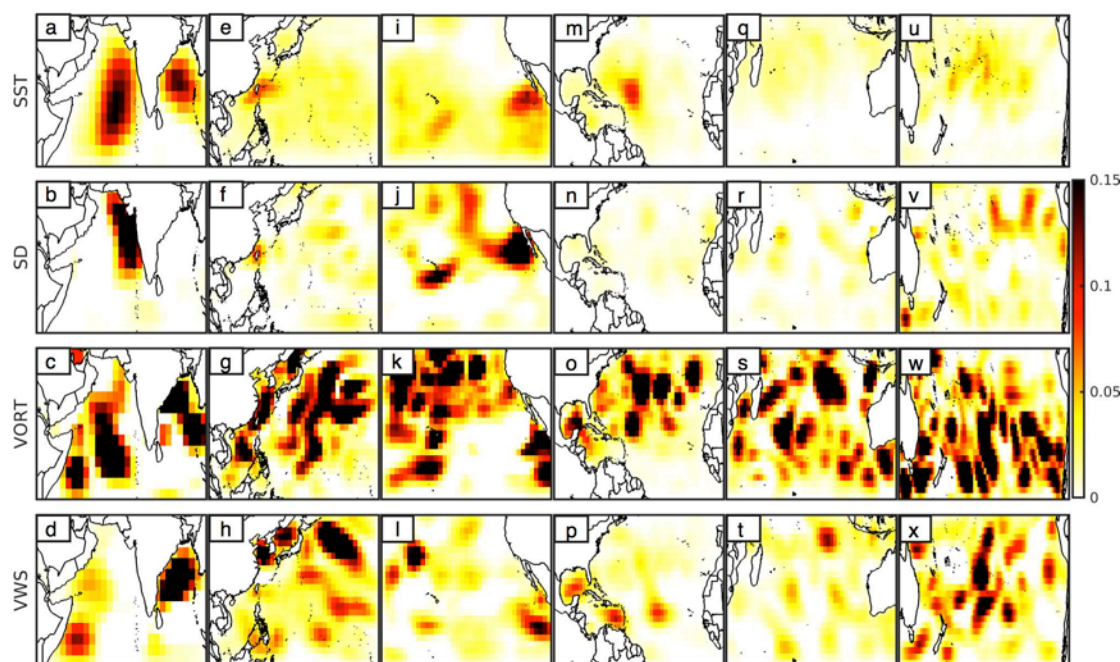

Figure 5: Occlusion sensitivity maps that highlight the relative importance in emulating seasonal NTC in different ocean basins. (a)-(d): Relative importance of SST, saturation deficit (SD), 850hPa vorticity and vertical wind shear in NIO, respectively. (e)-(h), (i)-(l), (m)-(p), (q)-(t), And (u)-(x) are similar, but for the relative importance of 4 variables in WNP, ENP, NAT, SIO and SPO, respectively. Areas in the map with higher values correspond to regions of input variables that contribute more significantly to impact the CNN prediction skills. Intuitively, the sensitivity map shows which area most affect the prediction RMSE when changed. Refer main text for details.

933
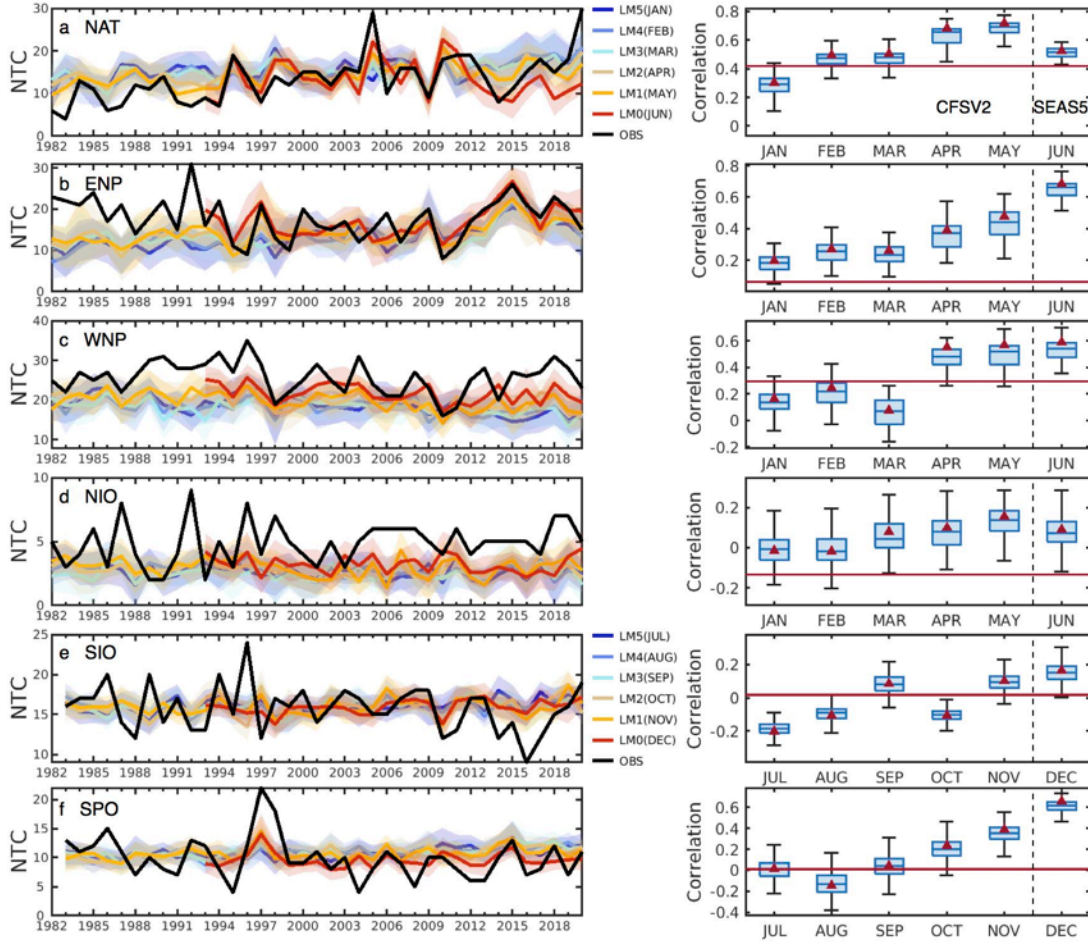

Figure 6: CNN based statistical-dynamical hybrid NTC seasonal predictions initialized at different lead month (LM). (a) Left: time-series of NAT NTC in observation (black) from 1982 to 2020, and CNN model predictions with the large-scale environmental conditions predicted form NCEP CFSv2 (LM1-5) and ECMWF SEAS5 (LM0) seasonal forecasts (refer to the figure legend). Note that, we downloaded SEAS5 from Copernicus Climate Change Service (C3S) Climate Data Store (CDS), which only provide seasonal prediction data since 1993. Color shading denotes the range across the CNN ensemble predictions. Right: boxplots of Pearson correlation coefficients between observation and CNN ensemble predictions at different lead months. Boxes show the first quartile, median and third quartile among the 600-member ensemble hybrid prediction, and the dashed vertical lines show the lowest and highest datum still within the 1.5 interquartile ranges. Maroon triangles denote the ensemble mean skill, and maroon horizontal line denotes persistence prediction skills. Persistence prediction is based on trailing 5-year average (WMO 2008). (b)-(f) Are similar to (a), but for NTC seasonal predictions in the ENP, WNP, NIO, SIO and SPO, respectively. Note that, we define SIO and SPO TC season as the period from prior November to following May. We did not show SAT results, given that seasonal mean SAT NTC is less than 0.1 in the observation.

950
951

37
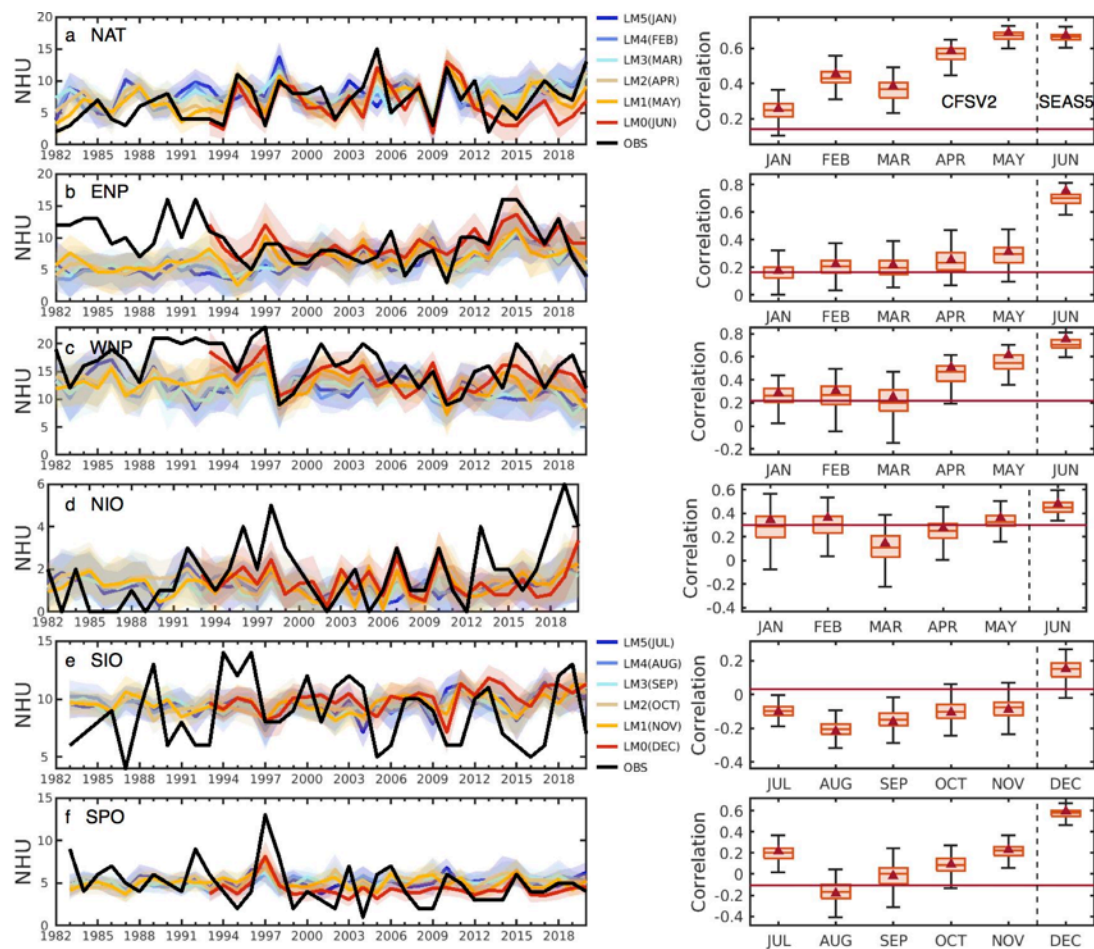

952
953    Figure 7: Similar to Figure 6, but for the NHU hybrid seasonal prediction skills.
954

955
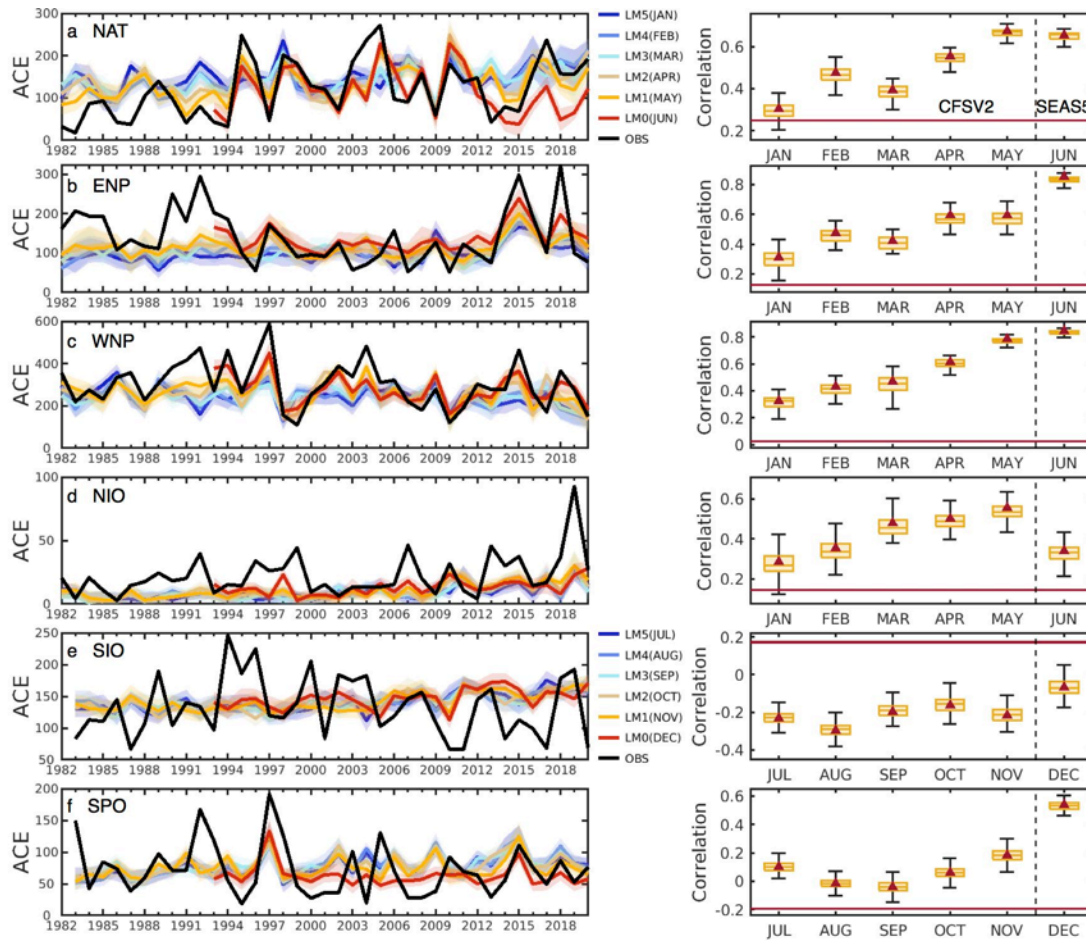

956  Figure 8: Similar to Figure 6, but for the ACE hybrid seasonal prediction skills.

957

958
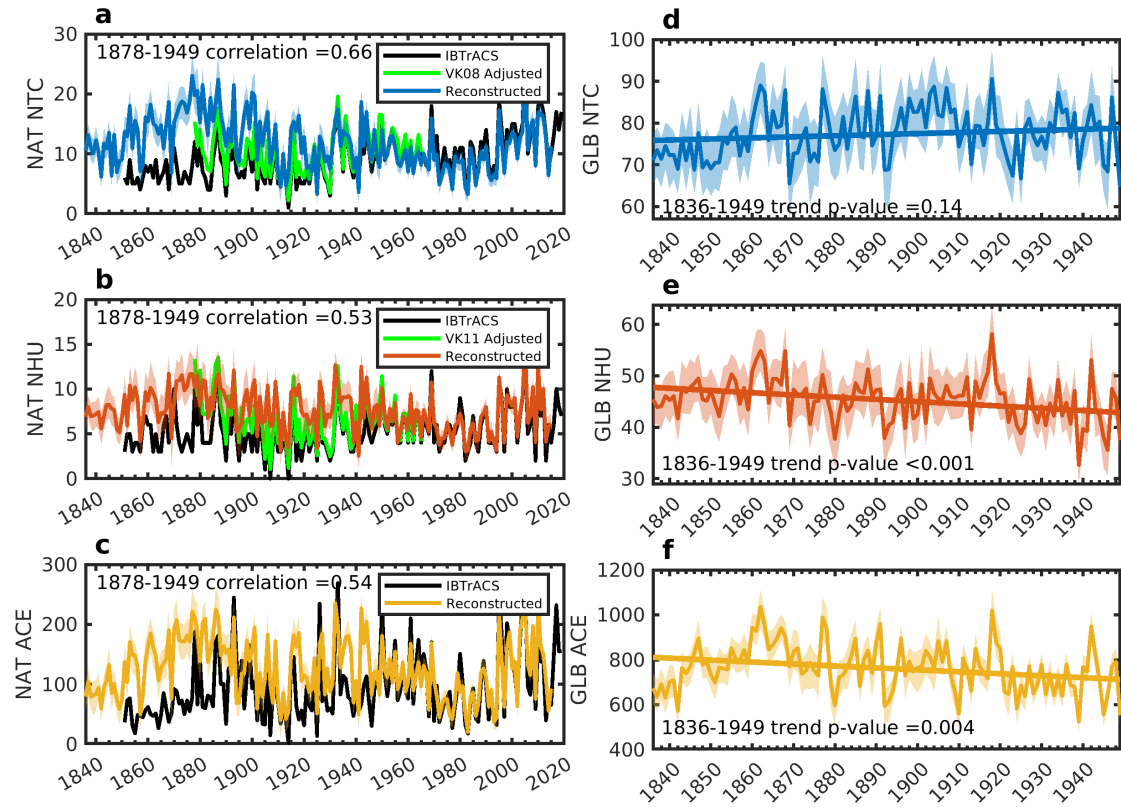

Figure 9: Time-series of NAT seasonal mean (a) NTC, (b) NHU, and (c) ACE from the IBTrACS observation in black, adjusted NTC and NHU observation based on Vecchi and Knutson (2008, 2011; VK08 and VK11 for short) in green, and CNN reconstruction based on the NOAA-CIRES-DOE 20th Century Reanalysis (20CRv3) for them period 1836-2015. Pearson correlation coefficient between linear-trend removed adjusted observations and CNN reconstructions during 1878-1965 are listed in each panel. Note that, data before 1950 are not used in the CNN training. (d)-(f) Are similar, but for global integration results. Linear trend during 1836-1949 and the p-values determined by the Mann-Kendall trend test are listed. We do not show global IBTrACS observation results as other TC active basins outside NAT only provide data since 1949.
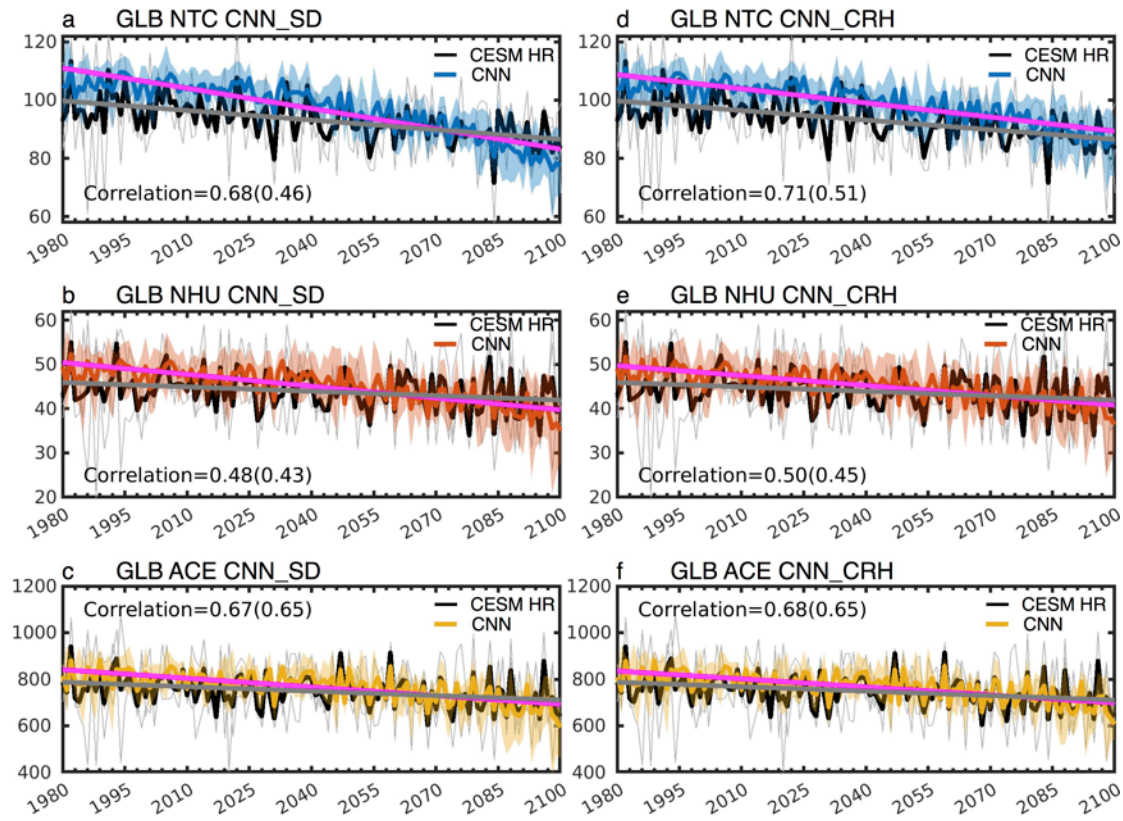

Figure 10: Time-series of 3-member ensemble mean CESM HR dynamically resolved TC activity (black) and CNN_SD (without transfer-learning, trained on climate model only) emulated global (a) NTC (blue), (b) NHU (red) and (c) ACE (yellow). Thin grey lines denote CESM HR 3 individual ensemble member, and color shadings indicate ranges across CNN ensembles. Pearson correlation coefficients between 1980-2100 are listed in each panel. The linear-trend-removed correlation coefficients are listed in the parentheses. All listed correlation coefficients are significant at 95% confidence level. Note that, CESM HR data after 1980 are not used in the CNN training. (d)-(f) Are similar, but using the alternative trained CNN model with column-integral relative humidity (CNN_CRH), rather than saturation deficient (CNN_SD), as the CNN moisture predictor variables.
Figure 11: Time-series of CNN_SD emulated anomalous NTC for (a) global, (b) Northern Hemisphere and (c) Southern Hemisphere integration with the large-scale environmental conditions projected by 36 different CMIP6 model under historical forcing and shared socio-economic pathway 5-8.5 (SSP585). Anomalies are computed as the departures from their 1980-1999 climatology. Black lines denote observation during 1980-2020, thick dark blue lines denote the multi-model mean of the CMIP6 models, and thin light blue lines denote the individual 36 CMIP6 model. Linear trends during 1980-2100 are plotted in magenta and listed in each panel; following by the fraction demonstrating number of individual models showing consistent sign of trend as to the multi-model mean. For example, 35 of 36 CMIP6 model project a decreasing trend with the mean trend of -0.17 per year emulated by the CNN_SD model. Note that, all multi-model mean linear trends are significant at 95% confidence level based on the Mann-Kendall trend test. (e)-(f) Are similar, but for the CNN_CRH emulated NTC projection.
Figure 12: Similar to Figure 11, but for the NHU projections.

Figure 13: Similar to Figure 11, but for the ACE projections.

Figure S1 to S6
Table S1

Supplementary Figure 1: Occlusion sensitivity maps that highlight the relative importance and contributions in emulating seasonal NHU in different ocean basins. (a)-(d): Relative importance of SST, saturation deficit (SD), 850hPa vorticity and vertical wind shear in NIO, respectively. (e)-(h), (i)-(l), (m)-(p), (q)-(t), And (u)-(x) are similar, but for the relative importance and contributions of 4 variables in WNP, ENP, NAT, SIO and SPO, respectively. Areas in the map with higher values correspond to regions of input variables that contribute more significantly to impact the CNN accuracy. Intuitively, the sensitivity map shows which area most affect the prediction RMSE when changed. Refer main text for details.
Supplementary Figure 2: Similar as to Supplementary Figure 1, but for occlusion sensitivity maps for ACE.
Supplementary Figure 3: Time-series of NAT seasonal mean (a) NTC, (b) NHU, and (c) ACE from the IBTrACS observation in black, adjusted NTC and NHU observation based on Vecchi and Knutson (2008, 2011) in green, and CNN reconstruction based on the ECMWF's Coupled Reanalysis of the Twentieth Century (CERA-20C) for them period 1901-2010. Pearson correlation coefficient between linear-trend removed adjusted observations and CNN reconstructions during 1901-1965 are listed in each panel. Note that, data before 1950 are not used in the CNN training. (d)-(f) Are similar, but for global integration results. We do not show global IBTrACS observation results as other TC active basins outside NAT only provide data since 1949.
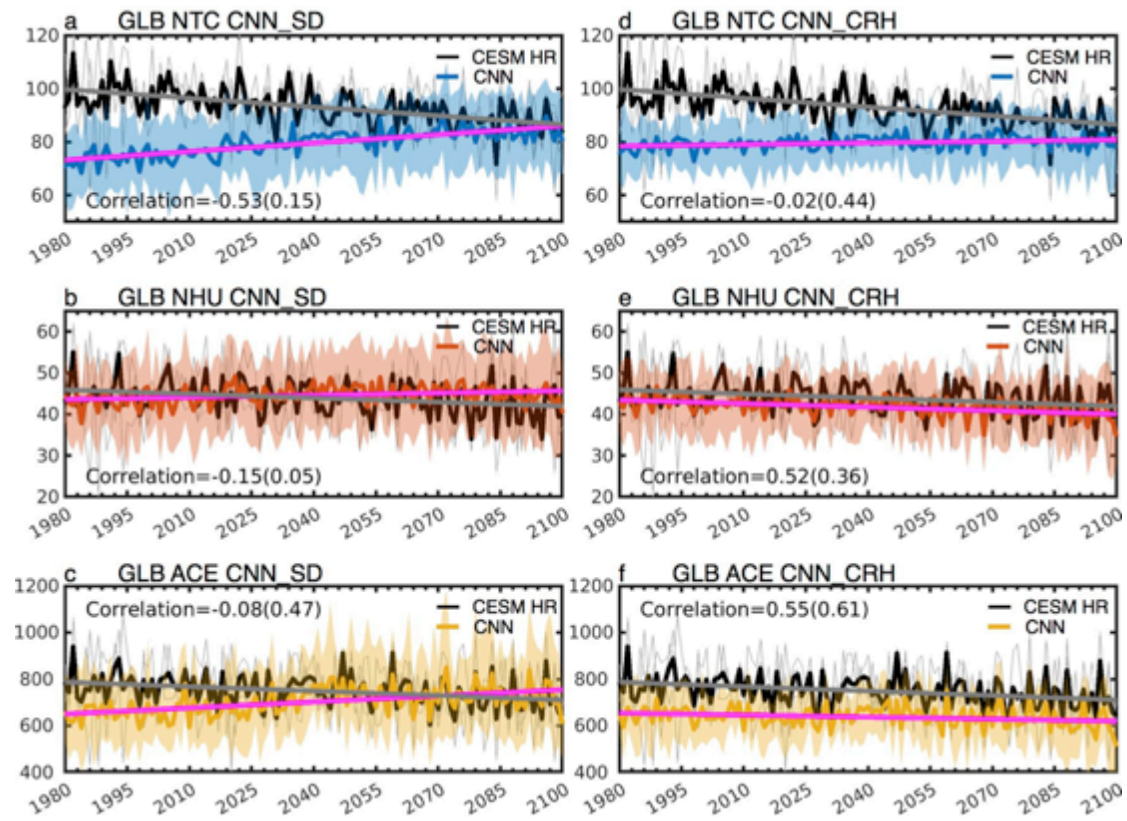

Supplementary Figure 4: Time-series of 3-member ensemble mean CESM HR dynamically resolved TC activity (black) and transfer-learned CNN_SD emulated global (a) NTC (blue), (b) NHU (red) and (c) ACE (yellow). Thin grey lines denote CESM HR 3 individual ensemble member, and color shadings indicate ranges across 600-member CNN ensembles. Pearson correlation coefficients between 1980-2100 are listed in each panel. The linear-trend-removed correlation coefficients are listed in the parentheses. Note that, CESM HR data after 1980 are not used in the CNN training. (d)-(f) Are similar, but using the alternative trained CNN model with column relative humidity (CNN_CRH), rather than saturation deficient (CNN_SD), as the CNN predictor variables.
Supplementary Figure 5: Time-series of CNN_SD emulated anomalous (a) NTC, (b) NHU, and (c) ACE in different ocean basins, with the large-scale environmental conditions projected by 36 different CMIP6 model under historical forcing and shared socio-economic pathway 5-8.5 (SSP585). Anomalies are computed as the departures from their 1980-1999 climatology. Standard deviation among 36 CMIP6 models are shown as shadings, while multi-model mean is plotted in lines. The number of individual models with consistent sign of trend as to the multi-model mean is shown in the legend. (e)-(f) Are similar, but for the CNN_CRH emulated CMIP6 projection.

Supplementary Figure 6: Similar to Supplementary Figure 5, but for the ratio of emulated NHU/NTC, and ACE/NTC.

Supplementary Table 1: 36 CMIP6 models utilized for the CNN future projections.
