33 **Abstract**

34 The strikingly diverse population dynamics of herbivorous small mammals, ranging from high-
35 amplitude, multi-annual cycles to relatively stable dynamics, have puzzled ecologists for a
36 century. Theory predicts that this diversity is shaped by density-dependent food web interactions
37 and stochastic weather events. Recent disrupted cycles through amplitude dampening have been
38 attributed to climate change. However, empirical testing has been hampered by the complexity of
39 the food webs in which these herbivores normally are found. Here we analyze population
40 dynamics of a grazing vole species in a uniquely simple high-Arctic food web without top-down
41 regulation. In accordance with theory, the population dynamics was mostly ruled by
42 overcompensatory density-dependence in winter that without environmental stochasticity would
43 have yielded seasonality driven high-amplitude 2-year cycles. In this simple food web, rain-on-
44 snow events disrupted cyclicality, but not through amplitude dampening. Our case study highlights
45 how food web structure may modify the impact of climate change on population dynamics.

46 **Introduction**

47 Theory suggests that contrasting population dynamics result from details in the pattern of
48 density-dependence, including its strength and shape, whether it acts instantly or with a delay,
49 and how it interacts with deterministic (seasonal) and stochastic (weather) components of the
50 prevailing or changing climate (Royama 1992; Stenseth 1999; Bjørnstad & Grenfell 2001; May
51 2001; Turchin 2003). Studies of small rodents have contributed much to elucidating the different
52 facets of density-dependent and density-independent population dynamics (Stenseth 1999;
53 Turchin 2003). A central topic has been what sort of density dependence yields the high-
54 amplitude, multi-annual population cycles - for which voles and lemmings have become so
55 renowned (Elton 1942; Finnerty 1981; Stenseth & Ims 1993; Krebs 2013). Based on time series
56 analyses, delayed-density dependence is reckoned as a main determinant of population cycles
57 (see Stenseth 1999 and Barraquand *et al.* 2017 for reviews), although overcompensatory direct
58 density dependence appears to be an alternative in some settings (Barraquand *et al.* 2014). As
59 rodent cycles are most prevalent in northern ecosystems with profound climatic seasonality
60 (Elton 1942; Ims & Fuglei 2005; Krebs 2013; but see Korpimäki *et al.* 2005; Lambin *et al.*
61 2006), several studies have emphasised that annual density dependence ought to be decomposed
62 into its seasonal components (Hansen *et al.* 1999a; Stenseth *et al.* 2003; Cornulier *et al.* 2013) -
63 both to accurately account for the density-dependent structure that underlies the observed
64 dynamics and to identify the season-specific biotic mechanisms that cause density dependence.
65 Considering seasonal dynamics is also crucial to assess the role of climatic stochasticity, because
66 such external forcing differs between summer and winter (Cornulier *et al.* 2013; Korpela *et al.*
67 2013). The role of climate forcing is now also accentuated by the recent collapses and

68 dampening of population cycles in several ecosystems that appear to be associated with ongoing
69 climate change (Ims *et al.* 2008; Gilg *et al.* 2009; Cornulier *et al.* 2013).

70 Linking density dependence to the biotic mechanisms that causally generate the diversity
71 of population dynamics patterns in small mammals have proved to be challenging. Most rodent
72 populations are imbedded in complex food webs, and hence, subjected to a multitude of biotic
73 interactions that could cause the different facets of density-dependent population growth. For
74 instance, delayed and direct density dependence may result from several trophic interactions as
75 well as intrinsic population mechanisms (Hansen *et al.* 1999b; Barraquand *et al.* 2014; Myers
76 2018). While field experiments have helped pinpointing some mechanisms (Ostfeld *et al.* 1993;
77 Ims & Andreassen 2000; Graham & Lambin 2002; Huitu *et al.* 2003; Fauteux *et al.* 2016), they
78 have been too short-term to be conclusive with respect to what generate different patterns of
79 multi-annual population dynamics.

80 Here we apply an approach that has proved useful for unravelling the effects of density
81 dependence and climatic stochasticity in herbivorous large mammals (e.g. Grenfell *et al.* 1998;
82 Coulson *et al.* 2001; Hansen *et al.* 2019), namely to target populations that are found in very
83 simple biotic settings. Hence, our study targets a high-arctic population of the graminivorous
84 (grass-eating) East European vole (*Microtus levis*) in a food web that lack biotic interactions (i.e.
85 predation) that cause complex density dependence in most other small mammal populations. By
86 combining statistical analyses of long-term, high-quality live-trapping data with simulations of a
87 population model parameterized from these data, we (1) test theoretical conjectures about what
88 sort of density dependence and resultant population dynamics is expected to emerge in such a
89 simple biotic setting and (2) assess how climatic stochasticity impinge on such density dependent
90 population dynamics. Finally, we point out how the insights from our case study shed new light

91 on the longstanding puzzle about what generate population cycles and how ongoing climate
92 change may influence these cycles.

93

94 **Methods**

95 *Study population*

96 Our study is located by Grumant in Svalbard (78.18°N, 15.13°E). This high Arctic location is
97 characterised by cool summers (July average: 5.9°C) and cold winters (January average -16.2°C)
98 with little precipitation (average 190 mm, period 1960-1990; Fjørland *et al.* 1997). Average daily
99 air temperatures at the nearby weather station (Longyearbyen airport, 13 km away), are typically
100 above 0°C in early-to-mid June - September. Winter temperatures are much more variable than
101 summer temperatures (Yoccoz & Ims 1999), with standard deviations of monthly mean
102 temperatures being 5.1°C for February and 0.9°C for July. In winter, temperature extremes can
103 vary between -44°C and 6°C, while in summer they vary between 0°C and 21°C (Fjørland *et al.*
104 1997). Rain-on-snow (ROS) events is a relatively frequent, stochastically occurring phenomenon
105 in Svalbard (Hansen *et al.* 2019) - calculated as the sum of precipitation at temperature above
106 1°C in the winter months November-April. ROS range from approximately 0 to 66 mm per year
107 and is most prevalent at the beginning of the winter period (November-January; Stien *et al.*
108 2012). ROS events have been found to strongly influence the population dynamics of all year-
109 round resident vertebrate populations in Svalbard (Hansen *et al.* 2013).

110 The East European vole belongs to one of the most speciose and widespread genera
111 (*Microtus*) of small mammals with presence in temperate, boreal and Arctic biomes (Tamarin
112 1985). Most *Microtus* species are graminivorous (i.e. grass-eating) and have multivoltine life
113 histories (e.g. multiple generation per year). The East European vole was accidentally introduced

114 in Svalbard in the first half of the 20th century (Fredga *et al.* 1990). The voles still have a highly
115 restricted distribution and are found in coastal slopes of bird cliffs in association with seabird
116 fertilized tundra vegetation dominated by graminoids, particularly Polar foxtail *Alopecurus*
117 *ovatus* (Elvebakk 1994). The best habitats have soils and lush grass vegetation on the top of
118 boulders that provide food, drainage and shelter for the fossorial voles.

119 There are no other small mammals present in Svalbard, which suggests virtually no
120 interspecific competition (Koivisto *et al.* 2007). The Arctic fox (*Vulpes lagopus*) is the only
121 terrestrial predator present, but acts as a generalist carnivore that mostly rely on seabirds in the
122 study area (Frafjord 2002). East European voles reproduce quickly with females observed to be
123 gravid as early as 17 days old (Yoccoz *et al.* 1993) and may live at high population densities
124 (>100 ind. ha⁻¹; Koivisto *et al.* 2007). The population dynamics of many *Microtus* voles have
125 been studied extensively on the European continent where they typically exhibit 3-4-yr multi-
126 annual cycles (Korpimäki *et al.* 2005; Lambin *et al.* 2006; Cornulier *et al.* 2013; Barraquand *et*
127 *al.* 2014).

128

129 *Live trapping*

130 East European voles were live-trapped during the years 1990-2007. Here, we analysed two data
131 sets. The main data set used for analysis of seasonal density dependence and demography was
132 obtained from one of the largest and lushest vole habitat patches in Svalbard; hereafter termed
133 Core area (Fig. 1). From 1990 to 1996, we used a trapping grid of 93 Ugglan Special multiple-
134 capture traps encompassing 4.5 ha of the Core area, while from 2002-2006 the grid was made of
135 74 traps and encompassed 2.8 ha. Traps were separated by approximately 20 m and placed by
136 burrow entrances wherever possible. Trapping of the Core area followed the robust design of

137 Pollock (1982) and consisted of three primary periods (late June/early July [hereafter termed
138 July] = P1; early August = P2; and early September = P3), each with 6 to 10 secondary periods,
139 except in 1990 when primary periods spanned only the first half of the summer. We used a
140 second, more long-term data set for assessing the annual population dynamics obtained from a
141 linear habitat on a ridge and vegetated part of the ravine at the western edge of the Core area
142 (hereafter termed Ridge; Fig. 1). The Ridge area was monitored with 30 traps in August during
143 1991-2007, with the same number of secondary periods as for the Core area. Oats and potatoes
144 were used as baits in the morning (07h00) and traps were checked twice during the day (13h00
145 and 19h00). Traps were deactivated during the last trapping period of the day. Captured voles
146 were marked by toe clipping, sexed and weighed. The study was conducted according to the
147 regulations for research in Svalbard during the study period.

148

149 *Density estimation*

150 The densities of the vole population in the Core and Ridge areas was derived by spatially-explicit
151 capture-recapture (SECR) models with the package *secr* in R (Efford 2020; R Core Team 2020).
152 Briefly, these models have the advantage of estimating capture probabilities based on the
153 distance separating the center of activities of an individual from a trap (Borchers & Efford 2008).
154 By using a two-parameter (i.e. probability of capture at the center of activities and a measure of
155 home range size) half-normal detection function, we obtained more accurate estimates of the area
156 effectively surveyed (Krebs *et al.* 2011). For the Core area, we used one null SECR model per
157 trapping period per year with the Huggins parameterisation to estimate density (Krebs *et al.*
158 2011). For the Ridge area, annual densities were obtained for the August trapping period only.
159 Densities of male and female adults (body mass ≥ 25 g) and sub-adults (body mass < 25 g;

160 Yoccoz *et al.* 1993) were derived from this general model. Because the movement of voles in
161 Svalbard is restricted by habitat, we used a 20 m buffer around traps to build the state-space that
162 is used to estimate effective sampling area. The Nelder-Mead algorithm was used for
163 optimisation of the likelihood in model fitting.

164

165 *Annual density-dependent structure and temporal variability*

166 We used the annual early August SECR density estimates from the Ridge area to assess the
167 density-dependent structure. We modelled ln-transformed densities from the 17-year time series
168 using a second-order autoregressive model (Stenseth 1999; Turchin 2003). Coefficients obtained
169 from this type of model inform about direct (β_{t-1}) and delayed density-dependence (β_{t-2}), and may
170 also be interpreted with respect to the presence of cyclic dynamics and cycle periods (Royama
171 1992). We observed zero vole densities in the Ridge area in 1996 and 2002 and the time series
172 was modelled using $\log(D_t + \Delta)$ with $\Delta = 1$. A range of values for Δ , from $\Delta = 0.2$ to $\Delta = 2$, were
173 investigated, but the choice of Δ was not found to affect parameter estimates and conclusions
174 substantially. We used the standard deviation of the log10 transformed time series as a metric for
175 the temporal variability (i.e. the amplitude) of the multiannual dynamics (*s*-index; Stenseth &
176 Framstad 1980). The *s*-index has been used both to define cyclic dynamics (index values > 0.5 ;
177 Henttonen *et al.* 1985) and to compare populations across environmental gradients (Hansson &
178 Henttonen 1985, 1988; Ehrich *et al.* 2020).

179

180 *Seasonal density dependence and climate effects on population growth*

181 We used the following model to explore patterns of variation in population growth in summer
182 and winter in the Core area:

183

$$184 \quad X_{t+1} = X_t * e^{r_t * \Delta t} \quad (1)$$

185

186 Where X_t is the true population density at time t , r_t is the population growth rate from t to $t+1$
187 and Δt is the time period from t to $t+1$ (in months). Furthermore, we modelled r_t as a linear
188 function of X_t , climatic stochasticity in winter (C_t , i.e. ROS) and residual stochastic variation in r
189 (process error, ε_t):

190

$$191 \quad r_t = \beta_0 + \beta_X * X_t + \beta_C * C_t + \varepsilon_t \quad (2)$$

192

193 where we assume that process error $\varepsilon_t \sim N(0, \sigma_r^2)$ and $\beta_0, \beta_X, \beta_C$ and σ_r^2 are parameters estimated
194 by the data. Measurement error was included in the model assuming a log normal distribution for
195 the densities estimated using the SERC model, D_t , giving:

196

$$197 \quad D_t \sim \text{lnorm}(\log_e(X_t), \sigma_{D,t}^2) \quad (3)$$

198

199 The log normal measurement error standard deviation, $\sigma_{D,t+1}$, was estimated using estimates of
200 the standard error of D_t ($\text{SE}(D_t)$) obtained in the SECR analysis:

201

$$202 \quad \sigma_{D,t} = \log_e((\text{SE}(D_t) / D_t)^2 + 1) \quad (4)$$

203

204 The model (equations 1-3) was fitted in JAGS version 4.2.0 (Plummer 2003). Point
205 estimates of r_t and associated 95 % credibility intervals presented in figures were obtained by

206 fitting a model for r_t (equation 2) with time fitted as a factor, i.e. $r_t = \beta_t$. In addition to parameter
207 estimates and associated 95% credibility intervals we report estimates of Bayesian R^2 for the
208 models (Gelman *et al.* 2019). The Bayesian R^2 was estimated as the mean of $R_t^2 = \text{var}(\text{fit}_i) /$
209 $(\text{var}(\text{fit}_i) + \text{var}(\text{residuals}_i))$, where i index the update number in the MCMC simulation, $\text{var}(\text{fit}_i) =$
210 $\text{var}(\beta_{0,i} + \beta_{X,i} * X_t + \beta_{C,i} * C_t)$ and $\text{var}(\text{residuals}_i) = \sigma_{r,i}^2$.

211 Analyses of population growth were done separately for the approximately 2.5 month
212 summer period (June/July-September) and for the approximately 9.5 month winter period
213 (September-June/July) as we expected the population dynamics to differ substantially in these
214 two seasons. In the winter we expected the amount of ROS to have effects on population growth
215 (Stien *et al.* 2012; Hansen *et al.* 2013).

216 Summer population growth could be estimated from the change in densities from
217 June/July (t) to August ($t + 1$) and from August ($t + 1$) to September ($t + 2$). Differences between
218 these periods were investigated by fitting period as a factor in the model for population growth
219 (equation 2). Population growth rates were not estimated for the summer of 1996, when there
220 were no voles captured in the study area, and 2002, when there were no voles captured in the
221 first and second primary trapping periods and an estimate of 1 vole per hectare (3 voles caught)
222 in the third primary period. The very low density estimates in September 2002 and the absence
223 of voles in 1996 implied adoption of methodological adjustments, that are detailed in
224 supplementary material, to allow growth rate estimates over the associated winters.

225 The timing of the primary trapping periods differed somewhat in 1990-1991 from
226 subsequent years. In 1990, all the trapping was early in the season and the time period from
227 primary period 1 to primary period 3 was only 0.7 months. We therefore only used data from
228 primary period 1 and 3 to estimate population growth, to get a time period that was more similar

229 to the other years ($\Delta t = 1.2-1.7$ months). In 1991 it was only 2 weeks between primary period 1
230 and 2 and we used only estimates from primary period 2 and 3 in the analyses.

231

232 *Model simulations of multiannual population dynamics*

233 We simulated the annual population dynamics linking summer and winter population growth
234 from:

235

$$236 \quad X_{a,t+1} = X_{s,t} * e^{r_{s,t} * \Delta t_s} \quad (5)$$

$$237 \quad X_{s,t+1} = X_{a,t} * e^{r_{w,t} * \Delta t_w} \quad (6)$$

238

239 where $X_{s,t}$ and $X_{a,t}$ is population density in the spring and autumn in year t respectively, $r_{s,t}$ and
240 $r_{w,t}$ are population growth rates (month^{-1}) in summer and winter respectively, and Δt_s and Δt_w
241 are the time periods of the summer and winter seasons respectively ($\Delta t_s + \Delta t_w = 12$).

242 Using equation (2), $r_{j,t}$ were modelled with parameters estimated from the data (Table 2).

243 Our baseline deterministic model included only density dependence ($r_{j,t} = \beta_{j,0} + \beta_{j,x} * X_{j,t}$) and
244 assumed 3 months of summer and 9 months of winter. The sensitivity of population dynamics to
245 changes in parameter values were evaluated using bifurcation diagrams and analyses of
246 autocorrelation.

247

248 *Demography*

249 The demographic structure of the population was analysed using SECR based estimates of
250 subadult and adult, male and female vole densities. Recruitment was determined by comparing

251 densities of subadults to adult female densities. We analysed densities of male and female voles
252 within age categories to detect sex differences.

253 Survival and maturation rates of subadult and adult, male and female voles were
254 estimated using multi-events models implemented in the software E-Surge (Choquet *et al.* 2009).
255 For the summer estimates were obtained for the periods of July-August and August-September.
256 The data did not allow demographic rates for the winter period (September-July) to be estimated,
257 because too few individuals captured in year t survived the winter and were recaptured year $t+1$.
258 The maturation rate is the probability of a subadult to develop into the adult stage from one
259 primary period to the next. Survival, maturation and detection probabilities were modelled as
260 functions of covariates using a logit link function. Year, period (July-August vs. August-
261 September) and sex were considered as covariates for all demographic rates. In addition, age
262 (subadults vs. adults) was considered in models for survival and detection rates. Furthermore, we
263 evaluated the effect of vole density, D_t , as an environmental covariate in models of survival and
264 maturation rates. Model selection was based on Akaike information criterion corrected for
265 overdispersion (QAICc; Anderson *et al.* 1994) and estimates used in the model simulations (see
266 below) were retained from the model judged most parsimonious model using AICc.

267 The effect of density on survival and maturation was first determined by whether the
268 covariate was significant in the most parsimonious, non-temporal model. If yes, we tested if the
269 variance explained by the covariate was significant by using an ANODEV with M_t being the
270 most parsimonious temporal model, M_c as being the most parsimonious model with density as a
271 covariate (possibly with an interaction density*time), and M_0 as the model without density or
272 time as a covariate (Grosbois *et al.* 2008).

273

274 **Results**

275 *Annual population dynamics*

276 The 1991-2007 time series of annual estimates of Eastern European vole densities from the
277 Ridge trapping area was characterised by high amplitude population fluctuations with 2 - 4 years
278 between subsequent crash years (Fig. 1). The population dynamics appeared to be stationary; i.e.
279 there were no evidence for temporal trends in mean or variance in densities over the 17 years.
280 The amplitude of the fluctuations (s-index=0.57) was within the range found in population time
281 series of cyclic Arctic lemming populations (Ehrich *et al.* 2020). However, in contrast to most
282 other Arctic populations, first (r = -0.39) and second-order (r = 0.02) autocorrelation coefficients
283 showed no evidence of cyclic dynamics.

284 A second-order autoregressive model supported only direct density dependence ($\beta_{t-1} = -$
285 0.46, 95% confidence interval [CI]: [-0.70, 0.02]), while delayed density dependence was
286 estimated to be close to zero ($\beta_{t-2} = -0.15$, 95% CI: [-0.65, 0.34]). These estimates suggest
287 population dynamics with dampened 2-year cycles (Royama 1992), and that sustained
288 fluctuations were upheld by the high unstructured error variance ($\sigma^2 = 1.3$).

289

290 *Seasonal density dependence*

291 The analysis of the seasonal population density estimates from the Core trapping area during
292 1990-1996 and 2002-2006 (cross-correlation of vole densities with the Ridge trapping area, r =
293 0.92; Fig. 1), showed that the summer population growth rates were all positive (Fig. 2 and 3a).
294 This suggests that the vole population densities remained below carrying capacity. Still, there
295 were evidence for density dependence in that population growth rates were negatively related to
296 density in the previous month (Table 1, Fig. 3a).

297 In contrast, winter population growth rates were negative in many of the years. The
298 negative population growth rates in winter were associated with both high vole densities in the
299 previous autumn and high levels of ROS in the winter (Table 1, Fig. 3b). Overall, the data
300 suggest strong population regulation from direct density-dependence in the winter period.

301

302 *Simulated population dynamics*

303 A deterministic version of a seasonal density-dependent model fitted to the data would generate
304 stable 2-year vole cycles. These 2-yr cycles were relatively robust to changes in climate severity
305 in winter, in that high ROS have to become the norm for a change to stable dynamics with a
306 single equilibrium density (Fig. 4a). The 2-yr cycle in the baseline model was also robust to
307 changes in season lengths as climate change would have to reduce the winter length to well
308 below 8 months for more complex dynamics to appear (Fig. 4b). However, the signal of the 2-yr
309 cycles deteriorated fast with increasing levels of stochastic process error (Fig. 4c). At the
310 observed levels of process error the expected second order autocorrelation was close to zero in
311 the model simulations ($r = 0.02$); i.e. similar to what was estimated from the time series data.
312 Finally, temporal variability as quantified by the s-index increased with increasing process error
313 (Fig. 4d).

314

315 *Demography*

316 Sub-adult male and female voles occurred at similar densities, with no evidence for a systematic
317 deviance from a 1:1 sex ratio (Fig. 5a). The sex ratio of adults approached a 2:1 female-bias at
318 high female densities (Fig. 5b). This pattern was consistent with strong density-dependent
319 regulation of adult male densities in summer, with growth rates close to zero at ~14 adult male

320 voles ha^{-1} (Fig. 5c). There was no strong evidence for adult female population growth to be
321 density-dependent ($\beta_D = -0.015$, $\text{CI}=[-0.034, 0.005]$). Recruitment in the population remained
322 also relatively stable across densities with a ratio of sub-adults to adult females being close to 1:1
323 (Fig. 5d).

324 Both survival and maturation rates varied significantly between years as well as among
325 demographic categories (sex and age) and summer periods (Supplementary material, Table S1,
326 Fig. S1) in a manner that contributed to the high process error in the summer population growth
327 (Table 1). Survival rate was density-dependent, and stronger in females than in males
328 (Supplementary material, Table S2, Fig. S2), whereas there was no evidence for density-
329 dependence in maturation rates (Supplementary material, Table S2, Fig. S3).

330

331 **Discussion**

332 Without significant top-down regulation from predators, the focal study system is essentially
333 reduced to a simple two-link food chain consisting of a multivoltine herbivore population and
334 their graminoid food plants in a profoundly seasonal environment. Here we have presented the
335 first empirical analysis of such an ecological system that so far only has been subjected to
336 theoretical investigations. Such systems have been modelled mechanistically in continuous time
337 to identify under which circumstances multiannual herbivore population cycles can be expected
338 (Oksanen 1990; Turchin & Batzli 2001). Moreover, theoreticians have thoroughly investigated
339 the dynamical properties of phenomenological discrete-time models with seasonal direct density-
340 dependence (Kot & Schaffer 1984), akin to the model we here parameterized with field data. The
341 core insight from this theory - and indeed also our empirical study - is that the profound
342 seasonality destabilises the dynamics of such simple systems (White & Hastings 2020). Profound

343 seasonality in terms of a long arctic winter without primary production implies that carrying
344 capacity in summer greatly exceeds that of the winter. Such environmental setting combined
345 with a multivoltine life history and a weakly density-dependent summer growth rate allows the
346 herbivore population to overshoot its winter carrying capacity, and thus induce violent
347 population crashes due to overcompensatory direct density dependence.

348 Interestingly, the continuous-time, plant-herbivore model analysed by Turchin and Batzli
349 (2001) with a graminoid-type plant regrowth function, multivoltine herbivore population
350 dynamics and high-arctic seasonality without stochasticity, generated 2-year cycles like our
351 baseline model. We are not aware that such short population cycles have ever been observed in
352 any mammal populations. Neither are we aware of any other cases of such high-amplitude, high-
353 frequency boom-bust vole population dynamics without a clear cyclic signal as we observed in
354 our high-arctic study system. In multivoltine rodents, cycle lengths typically vary between 3-5
355 years in ecosystems with profound seasonality, while non-cyclic populations often seen in
356 environments with less pronounced seasonality have such low-amplitude fluctuations that they
357 are termed stable (Hansson & Henttonen 1988; Bjørnstad *et al.* 1995). It is commonly assumed
358 that any cycle generating mechanism must induce delayed density dependence (Stenseth 1999;
359 Ims & Fuglei 2005; Barraquand *et al.* 2017; Myers 2018), although opinions differ about which
360 mechanisms are in place (Turchin *et al.* 2000; Gauthier *et al.* 2009). Seasonality is in itself a
361 source of delay in producer-consumer interactions (Oksanen 1990), but is expected to yield only
362 2-year cycles if the delay is less than a year. The rapid regrowth of graminoids (Turchin & Batzli
363 2001) – even after high vole peak densities and severe winter grazing (Klemola *et al.* 2000) –
364 prevents the one-year delay that generates the longer cycles often found in graminivorous voles.
365 We also notice that the lack of delayed density dependence in our study system does not support

366 that delays due to intrinsic mechanisms such as stress-induced maternal effects (Boonstra *et al.*
367 1998) were influential. In fact, the only demographic feature that could be attributed to intrinsic
368 regulation was adult sex ratio, which became more female biased with increasing population
369 density - as could be expected from the polygynous mating system of graminivorous voles (Ims
370 1987). Finally, our study supports previous studies proposing that the action of the almost
371 ubiquitous guild of specialist rodent predators in boreal and Arctic food webs normally cause the
372 delayed density dependence that was lacking in our study system (Hanski *et al.* 1993; Turchin *et*
373 *al.* 2000; Gilg *et al.* 2003). Indeed, the absence of specialist rodent predators in high-Arctic
374 Svalbard is the most likely cause of the exceptional vole population dynamics observed here.
375 Experimental predator removals (Ims & Andreassen 2000; Klemola *et al.* 2000; Fauteux *et al.*
376 2016) have never been conducted at sufficient spatial and temporal scale to investigate the
377 outcome on multiannual population dynamics.

378 A fundamental question in population ecology accentuated by global climate change is
379 how abiotic environmental variation can modify the effect of density-dependent biotic
380 interactions. Our study adds to previous studies showing that episodes of mild winter weather in
381 boreal and Arctic ecosystems may lead to population crashes in herbivores (Aars & Ims 2002;
382 Korslund & Steen 2006; Dominé *et al.* 2018) and disrupt population cycles (Ims *et al.* 2008;
383 Kausrud *et al.* 2008; Gilg *et al.* 2009; Korpela *et al.* 2013). Previous models has shown that
384 climatically disrupted population cycles in multivoltine rodents readily collapses to low-
385 amplitude fluctuations and hence stable populations dynamics in presence of both direct and
386 delayed density dependence (Ims *et al.* 2008; Kausrud *et al.* 2008; Gilg *et al.* 2009). Here we
387 have shown that population cycles in a simpler trophic system with only direct density-
388 dependence may also easily be disrupted by increasing climatic stochasticity, however, without

389 any dampening effect on the dynamics. Hence, our case study provides support to the general
390 conjecture that the impact of climate change on ecological systems is dependent on their
391 structure and hence can be expected to be diverse across time and space (Coulson *et al.* 2001;
392 Gilg *et al.* 2009; Korpela *et al.* 2013).

393

394 **Acknowledgements**

395 The following institutions financed the fieldwork in Svalbard: Research Council of Norway,
396 Governor of Svalbard, Nansen Endowment, French Polar Institute, and French Embassy of
397 Norway. The present study, which is a contribution from the Climate-ecological Observatory for
398 Arctic Tundra (COAT), was funded by Svalbard Environmental Protection Fund. The following
399 people contributed to the trapping of voles during the 18 summers in Svalbard: Harald Steen, Jon
400 Aars, Ottar N. Bjørnstad, Thomas Hansteen, Christophe Pelabon, Siw T. Killengreen, Edda
401 Johannesen, Harry P. Andreassen, Gry Gundersen, Thor Aasberg and Xavier Lambin.

567 **Tables**

568 Table 1. Parameter estimates for the best models for monthly population growth of Eastern
 569 European voles (equations 1-5) over winter and in the summer period and estimates of the
 570 Bayesian R^2 for the models. No rain-on-snow (ROS) effect was included in the model for
 571 summer population growth, giving no estimate of β_{ROS} .

Parameter	Winter		Summer	
	mean	95 % C. I.	mean	95 % C. I.
β_0	0.23	(0.14, 0.33)	0.64	(0.44, 0.83)
β_D	-0.0040	(-0.0058, -0.0024)	-0.0051	(-0.0095, -0.0006)
β_{ROS}	-0.0043	(-0.0074, -0.0014)	-	-
σ_r^2	0.005	(0.001, 0.020)	0.020	(0.005, 0.058)
Bayesian R^2	0.92	(0.73, 0.98)	0.40	(0.02, 0.76)

572 β_0 = intercept; β_D = coefficient for density at time t ; β_{ROS} = coefficient for effect of ROS; σ_r^2 =
 573 process error variance.

574 **Figure legends**

575 **Figure 1.** Picture of the Core and Ridge areas for live-trapping East European voles near
576 Grumantbyen on Svalbard (**a**) and time series of vole densities (**b**) estimated in August in the
577 Core area (gray shape, lines points, years 1990-1996 and 2002-2006) and the Ridge area (black
578 shape, lines and points, years 1991-2007). Error bars represent 95% confidence intervals.

579
580 **Figure 2.** Population density of the East European vole in the Core area near the Grumant area in
581 Svalbard (lines and points) and precipitations of rain on snow during the previous winter (Rain-
582 on-snow; black bars in **a** only). The total population densities are shown in **a**. In **b**, adult males
583 (solid blue circles and lines), adult females (solid red squares and lines), subadult males (open
584 pale blue circles and lines), and subadult females (open pale red squares and lines) are shown.
585 Densities were obtained using spatially-explicit capture-recapture models with the Huggins
586 parameterisation. Dotted lines indicate change in population size during winter. The thin grey
587 bands indicate winter when trapping was not conducted. The wide grey band between 1996 and
588 2002 indicate no trapping during that period. Error bars represent 95% confidence intervals.
589 Notice the difference in scale between **a** and **b**. In 1990, trapping periods were in early July, late
590 July, and mid-August. In 1991, trapping periods were early July, late July, and mid-September,
591 whereas for all other years trapping was done in the first part of each month.

592
593 **Figure 3.** Estimated monthly population growth rates (r) in summer in relation to population
594 density in month m (**a**) and monthly winter population growth rate in relation with population
595 density in year t measured in September (**b**) of East European voles. In **a**, filled points represent
596 the early summer period (July-August) and open points the late summer period (August-

597 September) each year. In **b**, the points represent average monthly growth over the period
598 September-July and point size reflect the amount of rain-on-snow (ROS, mm) that fell during the
599 winter. Error bars represent 95% confidence and credibility intervals along respectively the x and
600 y - axis. Parameter estimates for the regression lines (with 95% C.I.) are given in Table 1.
601 Horizontal dotted gray line mark $r = 0$, no change in population size.

602

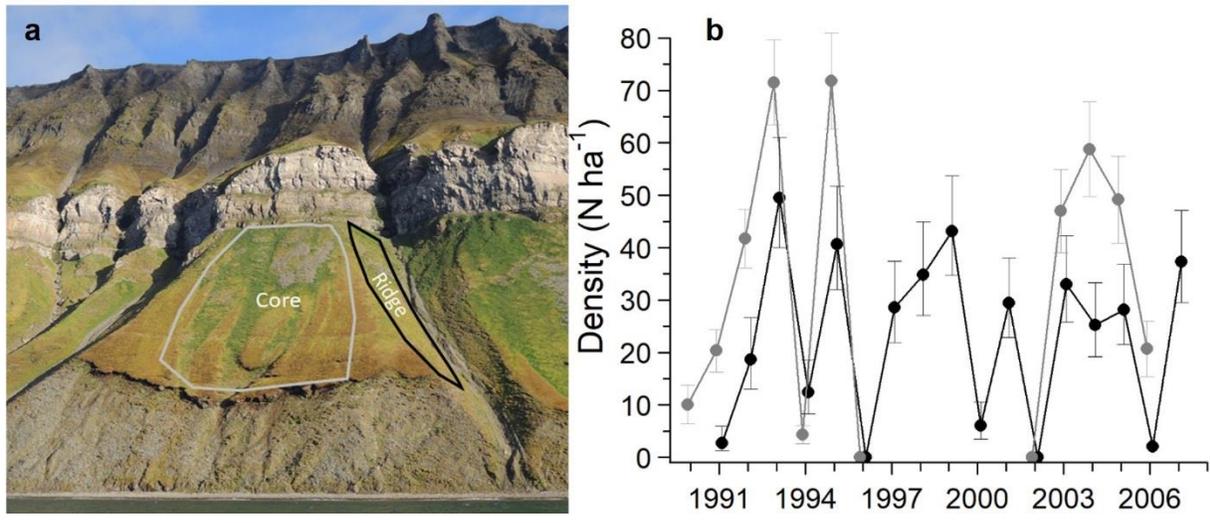

603 **Figure 4.** Simulated population dynamics in the East European vole in Svalbard. **(a)** Bifurcation
604 diagram for autumn densities for increasing fixed amounts of ROS every winter using the
605 population model with no process error ($r_{w,t} = \beta_{w,0} + \beta_{w,X} * X_{w,t} + \beta_{w,ROS} * ROS_t$, parameter
606 estimates in Table 1 but $\sigma_{i,r}^2$ set to zero). **(b)** Bifurcation diagram for the effect of changing the
607 length of the winter season (Δt_w) on autumn densities in the baseline population model with zero
608 rain-on-snow and process error (ROS = 0, $\sigma_r^2 = 0$). **(c)** Estimates of the second order
609 autocorrelation and **(d)** the amplitude of fluctuations (s-index) in autumn densities in the baseline
610 population model for increasing values of process error variance (σ_r^2) and ROS = 0. In **c** and **d**,
611 the long dashed line represents a model where process error only affects the summer population
612 growth, the short dashed line a model where process error only affects the winter population
613 growth, and the solid line represents a model where process error affects equally winter and
614 summer population growth. Estimates of process error variance in models without a ROS effects
615 were $\bar{\sigma}_{w,r}^2 = 0.014$ and $\bar{\sigma}_{s,r}^2 = 0.020$ for winter and summer, respectively. Estimated second order
616 autocorrelation in the Ridge area in August was 0.02, while the s-index was 0.57.

617

618 **Figure 5.** Demographic structure and density dependence based on sex and body size (i.e. sub-
619 adult vs. adults) of East European voles. Sex ratio displayed as **a** the density of sub-adult males
620 plotted against the density of sub-adult females and as **b** density of adult males plotted against

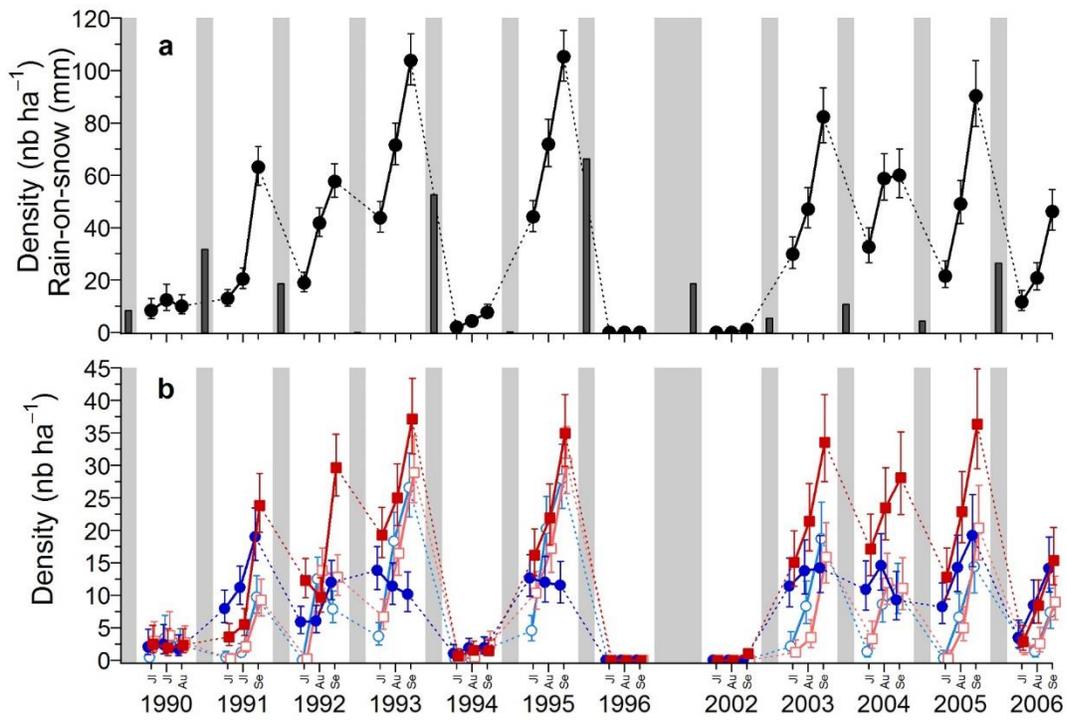

621 the density of adult females. In **c**, density-dependence in adult males in summer displayed as
622 estimated monthly population growth rate (from time t to $t+1$) in adult males plotted against the
623 density of adult males at time t . Estimates from the early (July-August) and late part of the
624 summer (August – September) are given by closed and open circles, respectively. The full line is
625 the regression line estimated using equations (1-5; $\beta_D = -0.043$, $CI=[-0.073, -0.009]$). Black
626 dotted lines are the 95% C.I. for the regression line and the grey dashed horizontal line represents
627 zero population growth. In **d**, recruitment as measured by the density of sub-adults is plotted
628 against the adult female population density. In **a**, **b** and **d**, the 1:1 dotted lines are drawn for
629 visual reference. Bars gives the 95% confidence intervals of estimated densities (**a-d**) and
630 population growth rates (**c**).

645

646 **Methodological adjustments adopted to handling low and zero population densities when**
647 **estimating of population growth**

648 In September 2002 there were only 3 voles caught and the density was estimated to 1 vole per
649 hectare. However, the mark-recapture analysis did not allow measurement error to be estimated
650 for this density estimate. To overcome this problem with a missing value for the uncertainty
651 associated with the density estimator in subsequent analyses we used the empirical least square
652 linear relationship between $\log(D_t)$ and $\log(\text{var}(D_t))$, $\log(\text{var}(D_t)) = -1.5253 - 0.9479 * \log(D_t)$, to
653 estimate $\sigma_{D,t}^2$ for the last observation in 2002.

654 In June/July 1996, no vole was caught giving an estimate of zero density of voles. No
655 vole was caught in the Core area also in the subsequent trapping periods in 1996, as well as the
656 nearby Ridge area. The most reasonable explanation for the zero observations in 1996 was
657 therefore local extinction in the trapping area, and not that a zero due to measurement error. The
658 previous winter had the highest levels of ROS in the dataset and the population density the
659 previous autumn was also the highest observed, so the handling of the zero observation in 1996
660 could affect estimates of the effect of density dependence and ROS on winter population growth
661 rates. In our estimation of population growth we imputed a small number for the zero
662 observation in June/July 1996. We evaluated the consequence of different choices for the
663 imputed value by fitting the model (equations 1-3) with imputed values for the density in
664 June/July 1996 in the range $\delta = [0.1, 1]$, where 1 vole per hectare is the lowest positive estimate
665 of the density of voles in the study area. Changes in the imputed value mainly affected estimates
666 of the effect of ROS, with increasingly negative estimates of β_C with decreasing δ (point

667 estimates decreasing from -0.0042 to -0.0052). Estimates of β_X (density dependence) were robust
668 to the choice of δ (point estimate range = (-0.0041, -0.0042)). In the results we use $\delta = 1$. This
669 value of δ gave similar parameter estimates to models fitted to data with the observation from
670 June/July 1996 excluded. However, it is noteworthy that more negative effect sizes of ROS are
671 also consistent with the data.

672

673 **Detailed results from the survival and maturation analyses**

674 The data supported a model for survival that included an additive effect of year, and an
675 interaction effect between trapping period, age, and sex (Table S1). Apparent survival rates were
676 highest for adult females (~75-85%/month), whereas sub-adult males had the lowest apparent
677 survival rates (~15-65%/month; Fig. S2). Adult females showed no change in survival rates
678 between the early (July-August) and late (August-September) summer periods. For the other
679 demographic groups of voles survival rates were lower in late summer than early summer
680 (Supplementary material, Fig. S1). This period effect in the survival of males and juvenile
681 females, as well as high survival estimates for the years with very low densities (1990 and 1994),
682 was consistent with density dependent survival density at t and survival between t and $t + 1$ (Fig.
683 S2). The ANODEV confirmed that the survival was negatively affected by density, but this
684 effect was more pronounced in males than females ($\beta = -0.025$, 95% CI=[-0.036, -0.013]; Table
685 S2, Fig. S2).

686 Maturation rates varied between years and with an interaction effect between trapping
687 period and sex (Table S1, Fig. S1). We found no significant relationship with density at time t
688 based on the most parsimonious, non-temporal model ($\beta = 0.006$, 95% CI: [-0.011: 0.023]; Table
689 S2; Fig. S3). Both sexes had high maturation rates for the July-August period, with males having

690 a 100% maturation probability in all years in this first part of the summer (Fig. S1). Maturation
691 rates were substantially lower in the latter part of the summer (August-September), and males
692 tended to have lower maturation rates than females in this period (Fig. S1).

693

694

695 Table S1. Ranking of models to test for the effects of time and density on survival (φ) and
696 transition (ψ ; maturation) rates of East European voles. The formulae of each model (i) is shown
697 along with its number of parameters (K), ranking parameter ΔQAICc_i , and model weight (w_i).
698 We modelled detection the same way for all models with additive effects of period (t), year, age,
699 and sex. The models that are shown represent those with the highest statistical support (ΔQAICc_i
700 < 2) for the three hypotheses being tested. Time-dependent models shown are those with a
701 $\Delta\text{QAICc}_i < 4$ and the one ranked right after. For the density-dependence analyses, we present the
702 models with the highest support without temporal effects and ΔQAICc_i are calculated based on
703 the top time-dependent model.

Model				
Type	φ	ψ	K_i	ΔQAICc_i
Time-dependent	year+t.f.sex	year+t.sex	44	0.00
	year+t.sex+f.sex	year+t.sex	42	4.05
Density-dependent survival	D.sex+f.sex	year+t.sex	33	9.87
	D.f.sex+f.sex	year+t.sex	35	10.86
	D+sex	year+t.sex	32	11.22
Density-dependent maturation	year+t.f.sex	D+sex	34	58.54
	year+t.f.sex	D.sex+sex	35	59.08

704 Note: covariates on detection probabilities were the same for all models and included additive
705 effects of year, primary period, state (subadults, adults), and sex.

706 t = primary period (July-August, August-September); D = relative density (low, intermediate,
707 high); f = state; + = additive effect; . = interactive effect.

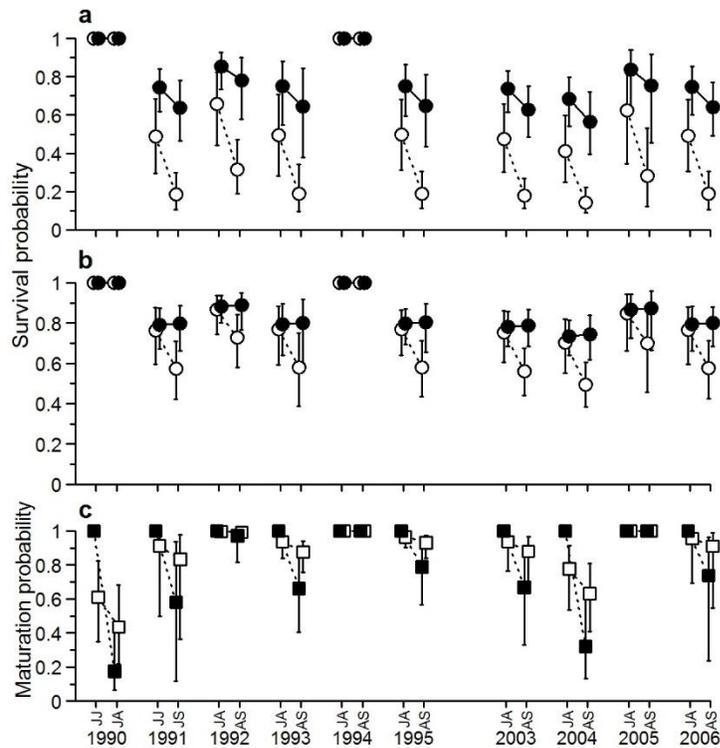

708

710 Table S2. Analysis of deviance (ANODEV) for models without temporal effects to assess
 711 density-dependence in survival (φ) and maturation (ψ) of East European voles.

Model				
Response variable	φ	ψ	<i>F</i> -value	<i>p</i> -value
Survival	D.sex+f.sex	year+t.sex	3.299	0.043
Maturation	year+t.f.sex	D+sex	6.109	0.018

712 Note: Model comparisons for the ANODEV were based on the full time-dependent model ($\varphi \sim$
 713 year+t.f.sex, $\psi \sim$ year+t.sex, $p \sim$ year+t+f+sex; $K = 44$) and the simplified model without time or
 714 density as a covariate on survival ($\varphi \sim$ f.sex, $\psi \sim$ year+t.sex, $p \sim$ year+t+f+sex; $K = 31$) or
 715 maturation ($\varphi \sim$ year+t.f.sex, $\psi \sim$ sex, $p \sim$ year+t+f+sex; $K = 33$).

716

717

718 Figure S1. Summer survival estimates of adult (black circles) and sub-adult (white circles) male

719 (a) and female (b) East European voles and maturation probabilities (c) of sub-adult males

720 (white squares) and females (black squares) throughout the years of sampling. Data points are

721 slightly displaced on the x-axis to make confidence intervals more visible. The gap between

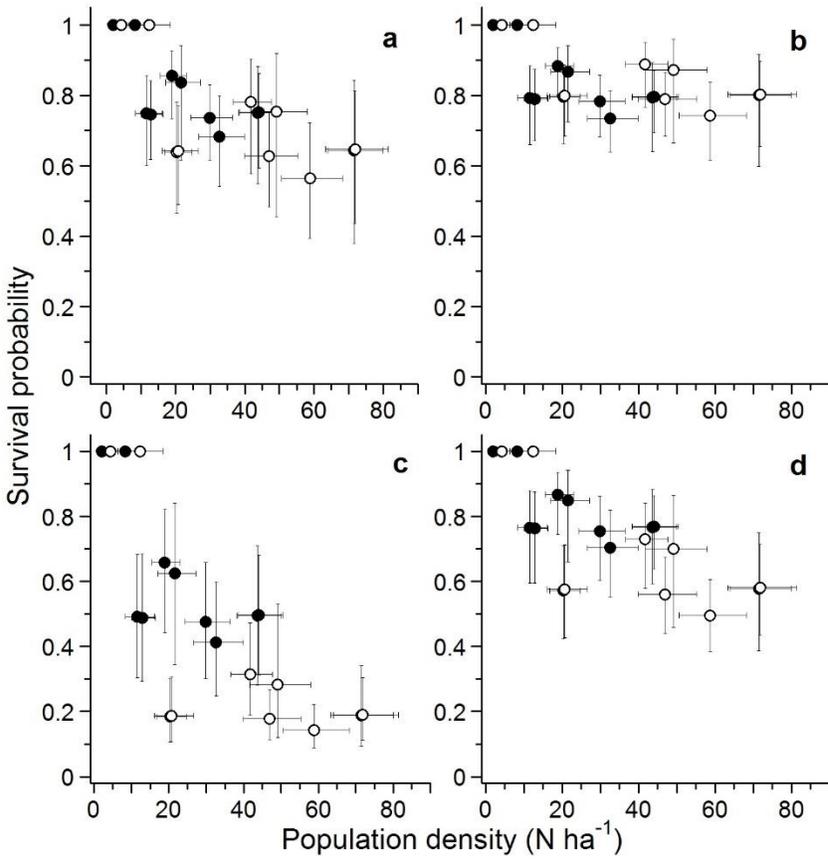

722 1995 and 2003 indicate no data available for summers of 1996-2002 due to sample size being too

723 low or trapping occurred only in August. Error bars are 95% confidence intervals. JJ: early July

724 to late July; JA: late July (1990 only) or mid-July (all other years) to mid-August; JS: late July to

725 mid-September; AS: mid-August to mid-September.

726

727

728 Figure S2. Estimates of survival rates in East European voles between t and $t+1$ of adult males

729 (a), adult females (b), subadult males (c), and subadult females (d) in relation with population

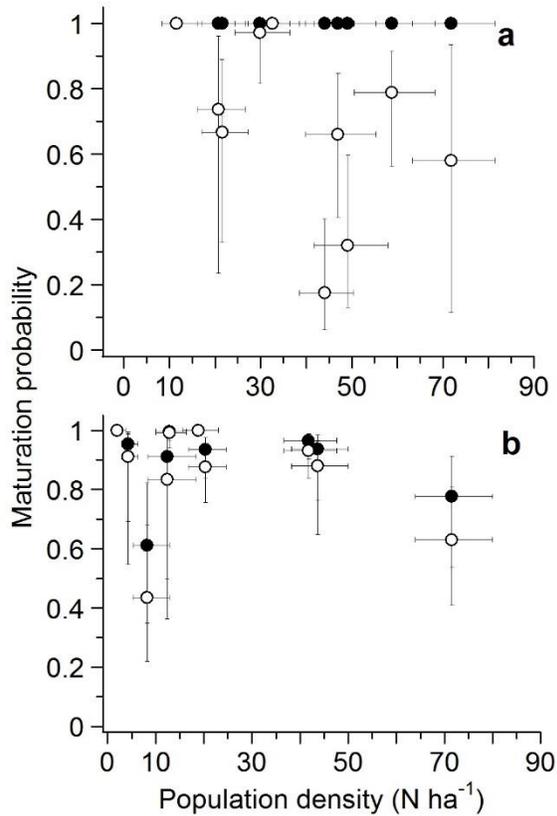

730 density at t from the most parsimonious model (Table S1, time-dependent model $\varphi =$

731 $f(\text{year}+t.f.\text{sex})$). Filled points represent the period of July-August and open points the August-

732 September period, error bars represent 95% confidence intervals.

733

734

735

736 Figure S3. Estimates of maturation rates in East European voles for subadult males (**a**) and
 737 females (**b**) from a model with an additive effect of year, and an interaction effect between live-
 738 trapping period and sex ($\psi = f(\text{year} + t.\text{sex})$, Table 1). Filled points represent the period of July-
 739 August and open points the August-September period, error bars represent 95% confidence
 740 intervals. Correlation coefficients are given using all the data points (r.all) and excluding the
 741 estimates of $\psi = 1$ (r.sub).
