13   **Abstract.** We use 214410 hourly observations of transpolar voltage, Φ_{PC}, from 25 years'
14   observations by the SuperDARN radars to confirm the central tenet of the Expanding-
15   Contracting Polar Cap model of ionospheric convection that Φ_{PC} responds to both dayside
16   and nightside reconnection voltages (Φ_D and Φ_N). We show Φ_{PC} increases at a fixed level of
17   the nightside auroral electrojet AL index with increasingly southward IMF (identifying the
18   well-known effect of Φ_D on Φ_{PC}) but also with increasingly negative AL at a fixed southward
19   IMF (identifying a distinct effect of Φ_N on Φ_{PC}). We also study the variation of Φ_{PC} with
20   time elapsed Δt since the IMF last pointed southward and show low/large values occur when
21   ($-AL$) is small/large. Lower numbers of radar echoes, n_e, mean that the "map-potential" re-
22   analysis technique used to derive Φ_{PC} is influenced by the model used: we present a
23   sensitivity study of the effect of the threshold of n_e required to avoid this. We show that for
24   any threshold n_e, Φ_{PC} falls to about 15 kV for Δt greater than about 15 hours, indicating any
25   viscous-like voltage Φ_V is considerably smaller than this. It is shown that both Φ_{PC} and
26   ($-AL$) increase with increased solar wind dynamic pressure p_{SW}, but not as much as the mid-
27   latitude geomagnetic index am. We conclude p_{SW} increases both Φ_D and Φ_N through
28   increasing the magnetic shear across the relevant current sheet but has a larger effect on mid-
29   latitude geomagnetic indices because of the effect of additional energy stored in the tail lobes.

1. Introduction.

This paper studies the Expanding-Contracting Polar Cap (ECPC) model of ionospheric convection excitation (*Cowley and Lockwood*, 1992) using an unprecedentedly large dataset of observations of the transpolar voltage Φ_{PC}, also known as the cross-cap potential difference. The ECPC model predicts that Φ_{PC} at any one instant depends on the reconnection voltage in the cross-tail current sheet Φ_N as well as that at the dayside magnetopause Φ_D.

One specific aim is to re-create two scatter plots from surveys of Φ_{PC} that have been of great importance to our understanding of the excitation of ionospheric polar convection by the solar wind flow, but here using a very much larger dataset of observations. The first of these scatter plots shows the dependence of Φ_{PC} on the northward component B_Z of the Interplanetary Magnetic Field (IMF) in the Geocentric Solar Magnetospheric (GSM) reference frame (*Reiff et al*., 1981; *Cowley,* 1984*; Boyle*, 1997; *Hairston et al*., 1998; *Milan et al.,* 2004; *Liu et al*., 2019). The second scatter plot shows the dependence of Φ_{PC} during northward IMF ($B_Z > 0$) on the time elapsed since the IMF was last southward (*Wygant et al.*, 1983). We also aim to use the large dataset, which covers more than a whole Hale solar magnetic cycle, to extend our understanding of the separate effects of reconnection in the magnetopause and the cross-tail current sheet by comparisons with the behaviour of the AL auroral electrojet index and to investigate the separate effects of solar wind dynamic pressure on Φ_D and Φ_N.

1-i. Transpolar voltage, steady state and non-steady-state convection

Magnetospheric convection (the circulation of plasma and frozen-in magnetic field) is at the heart of our understanding of the response of geomagnetic activity and terrestrial space weather to the transfer of energy from the solar wind into the magnetosphere. Directly-driven geomagnetic responses, historically called "Disturbance Polar-2" or "DP-2", are usually dominated by eastward currents in the afternoon sector polar ionosphere and detected as positive enhancements of the AU auroral electrojet index. DP-2 currents correlate highly with solar wind forcing at short response delays (*Nishida*, 1968a; b; *Lockwood et al.*, 1986; *Etemadi et al*., 1988; *Todd et al.*, 1988). These are driven responses to magnetic reconnection in the dayside magnetopause current sheet which generates open magnetospheric field lines (*Consolini and De Michelis*, 2005; *Finch et al.*, 2008; *Echer et al.*, 2017), the voltage Φ_D being the magnetic flux transfer rate from the closed to open magnetospheric field-line

60   topology.   The open field lines generated are swept into the geomagnetic tail by the solar

61   wind flow where they accumulate, storing energy there.   These open field lines in the tail are

62   subsequently re-closed in bursts of reconnection in the cross-tail current sheet, giving the

63   storage-release responses of geomagnetic activity ("DP-1") after a longer lag time than for the

64   DP-2 response (*Baker et al.*, 1983; *McPherron et al.*, 1998; *Klimas et al.*, 1992; 1994; *Finch*

65   *et al.*, 2008).   The DP-1 response is dominated by the effects of the westward auroral

66   electrojet current across midnight in the substorm current wedge and seen as negative

67   perturbations of the *AL* auroral electrojet index.   The voltage Φ_N is the magnetic flux transfer

68   rate from the open to the closed magnetospheric field-line topology.   The storage-release

69   response is often described in terms of the magnetospheric substorm cycle (e.g., *Baker et al.*,

70   1997; *McPherron et al.*, 1998).   A review of the development of our understanding of the

71   relationship of magnetospheric flux transport, the Dungey convection cycle and substorms has

72   been given by *McPherron* (2020) and a review of the associated energy flow through the

73   magnetosphere has been given by *Lockwood* (2019).

74   Being at the foot of magnetospheric field lines and, like the magnetosphere, being of high

75   magnetic Reynolds number, the frozen-in flux theorem applies in the polar ionospheric F-

76   region and topside ionosphere. Hence these regions reflect the circulation of frozen-in flux in

77   the magnetosphere (ionospheric convection).   However, there is one key difference between

78   the flows in the magnetosphere and in the ionosphere. The magnetosphere is compressible, a

79   fact that the storage-release system depends upon.   On the other hand, the ionosphere is

80   incompressible, in the sense that the magnetic field there is constant to within a very small

81   factor, such that even a very large geomagnetic disturbance is only a very small fraction of the

82   intrinsic geomagnetic field (for example, 1000 nT is less than a 2% perturbation).   The reason

83   for this is the ionosphere's close proximity to the currents in the Earth's interior that generate

84   the geomagnetic field.   This difference means that during substorm growth phases, when

85   energy is accumulating in the near-Earth lobes of the magnetospheric geomagnetic tail

86   because the field there is growing (and to some extent also because the lobes are expanding in

87   cross-sectional area as the tail flares), the ionospheric footprint of the open field lines of the

88   lobes (the open polar caps) must be expanding in area (*Holzer et al.*, 1986; *Lockwood et al.,*

89   1990; *Lockwood and Cowley,* 1992, *Milan et al*., 2003; 2009; 2012; *Huang et al.*, 2009).

90   *Siscoe and Huang* (1985) showed how expanding "adiaroic" segments polar cap boundaries

91   (meaning "not flowing across", i.e., not mapping to a magnetospheric reconnection site)

92 would influence the pattern of ionospheric convection. This concept was used by *Cowley and*

93 *Lockwood* (1992) to show how ionospheric convection is driven by both the generation and

94 destruction of open flux (the "Expanding-Contracting Polar Cap", ECPC model). This is

95 different to the magnetosphere, where flows are driven by the solar wind flow, pressure

96 balance and the magnetohydrodynamic (MHD) curvature force that acts to straighten bent

97 field lines. The ECPC concept is supported by detailed comparisons between theory and

98 observations of how patches of newly-opened flux, generated by magnetopause reconnection

99 bursts, evolve poleward (*Cowley et al.,* 1991a; *Lockwood et al.*, 1993; *McWilliams et al*.,

100 2000; *Throp et al*., 2005; *Lockwood et al.,* 2006). The result of these considerations is that

101 ionospheric convection is not, in general, a straightforward image of the magnetospheric

102 circulation and the two are decoupled by induction effects – changes in the magnetic field

103 between the magnetosphere and the ionosphere which, by Faraday's law, give a curl in the

104 electric field (*Lockwood et al*., 1990; *Lockwood and Cowley*, 1992; *Lockwood and Morley*,

105 2004).   In steady-state, the electric field becomes curl-free and electrostatic potentials do map

106 down magnetic field lines. In addition, in steady state the adiaroic boundaries are not moving.

107 Steady state applies when data are averaged over a long enough timescale; however, theory of

108 substorm growth and expansion predicts that it will not apply to the timescales of a few

109 substorm cycles or less. That is not to say that balanced reconnection events, when dayside

110 and nightside reconnection voltages are approximately equal, do not occur (*DeJong et al.,*

111 2008, *Lockwood et al*., 2009): these can occur by chance but, probably more often, they occur

112 because changes in the dayside reconnection voltage are sufficiently slow, such that it is never

113 greatly different to the lagged nightside voltage response (*Milan et al*., 2021). Surveys by

114 *Lockwood et al.* (2009) and *Milan et al.* (2021) have looked at the relative occurrence of

115 substorm cycles and quasi-balanced reconnection. Note that the ECPC model is the general

116 case as it can predict quasi-steady, quasi-balanced reconnection (if the interplanetary

117 conditions driving dayside reconnection vary slowly enough) as well substorm cycles. On the

118 other hand, balanced reconnection is not the general case as it cannot predict substorm cycles

119 (nor is there any known mechanism that can act to balance the reconnection rates at any one

120 instant). *Lockwood* (1991) pointed out that the motion of adiaroic convection reversals

121 boundaries means that they are smoothed out in average patterns of convection. On

122 timescales shorter than the substorm cycle of polar cap expansion and contraction,

123 ionospheric convection reflects both the DP-2 and DP-1 current systems and displays the

124 response delays associated with both (respectively a few minutes and 30-60 min). In addition,

125 because of a combination of ionospheric incompressibility and the antisunward motion of

126 open field lines, the response delay varies with location, increasing with distance away from

127 noon (*Lockwood et al.*, 1986; *Saunders et al.*, 1992; *Lopez et al.*, 1999; *Morley and*

128 *Lockwood*, 2005).

129 Convection is often quantified by the transpolar voltage Φ_{PC} between convection reversal

130 boundaries in the ionosphere on the dawnside and the duskside of the polar cap (*Reiff et al*.,

131 1981; *Cowley,* 1984*; Boyle*, 1997; *Hairston et al*., 1998; *Liu et al*., 2019). This parameter is

132 measured by spacecraft in high-inclination, Low-Earth Orbit (LEO) by integration of the

133 observed "along-track" component of the electric field along the satellite path between the

134 two dominant Convection Reversal Boundaries (CRBs). That electric field can be either

135 directly measured or derived from observations of the vector magnetic field, $\vec{B}$ and the plasma

136 flow $\vec{V}$ and using the equation of ideal MHD $\vec{E} = -\vec{V} \times \vec{B}$ which applies to a very high degree

137 of accuracy even in the F-region ionosphere because of the high magnetic Reynold's number

138 (*Hanson et al.,* 1994).   Hence by integrating the along-track electric field (corresponding to

139 the cross-track drift) between the two main CRBs, the transpolar voltage Φ_{PC} is measured for

140 that satellite path. The quantity Φ_{PC} is often accurately called the "polar cap potential drop",

141 but also frequently (but inaccurately) referred to as the "cross-cap potential" or "polar cap

142 potential". Strictly speaking, it is a potential difference, i.e., a voltage, and this semantic point

143 has real physical significance to understanding because, by Faraday's induction law, a voltage

144 is synonymous with magnetic flux transfer rate whereas a potential is not.   Hence, we here

145 use the term "transpolar voltage" for Φ_{PC} and note that it is the rate at which magnetic flux is

146 transferred across the polar cap. One convention that can be used is that positive transpolar

147 voltage means that the dawnside CRB potential exceeds the duskside CRB potential (i.e., the

148 electric field is from dawn to dusk), and this applies most of the time because net flux transfer

149 is from the dayside to nightside. The reason for this is that open flux is, by definition,

150 embedded in the solar wind flow and the solar wind is always transferring that open flux

151 antisunward and, during even the longest intervals of northward IMF, the open flux never

152 decays away. This antisunward flux transport remains dominant during northward IMF

153 despite interruptions by intervals of sunward flow of some open flux tubes caused by them

154 being reconfigured by lobe reconnection taking place at the magnetopause at the sunward

155 edge of the tail lobes (see review by *Lockwood and Moen*, 1999).   In terms of

156   magnetospheric configuration and voltages, this means the geomagnetic tail is always present

157   and so magnetic shear is always present between the two tail lobes giving some level of

158   magnetic reconnection in the associated cross-tail current sheet. In addition, reconnection at

159   the low-latitude dayside magnetopause (i.e., between the magnetic cusps) that opens

160   geomagnetic field lines has been observed to continue (at a low level) during intervals of

161   northward IMF (*Chandler et al.*, 1999; *Fuselier et al.*, 2000).

162   Figure 1 is a schematic of the three drivers of convection in the magnetosphere and

163   ionosphere during southward IMF. This is adapted from *Cowley* (1982), but with the addition

164   of a reconnection X-line in the cross-tail current sheet (in green, the voltage across which is

165   Φ_N) that re-closes open field lines. This is included here because in the ECPC model (*Cowley*

166   *and Lockwood*, 1992) it contributes to the ionospheric transpolar voltage Φ_{PC}. The ECPC

167   model predicts that at any one time, the effect of Φ_N combines with the effect of the

168   reconnection voltage Φ_D along the dayside magnetopause reconnection X-line (in red) which

169   generates open field lines. The third source of Φ_{PC} illustrated here is "viscous-like"

170   momentum transfer across the magnetopause onto closed field lines that generates a total

171   antisunward magnetic flux transfer of closed flux of voltage Φ_V in the low latitude boundary

172   layers (LLBL) on the dawn and dusk flanks of the magnetosphere. Figure 2 is a schematic of

173   ionospheric flow patterns that is compatible with Figure 1 and the ECPC model in general.

174   Figure 2a shows the special case of steady-state ($\Phi_D = \Phi_N$) with some viscous-like flow

175   cells ($\Phi_V > 0$) and is as in the schematic used by *Cowley* (1982).   Figures 2b and 2c are

176   examples of ECPC model predictions for, respectively, an expanding and a contracting polar

177   cap. For polar cap expansion $\Phi_D > \Phi_N$ and $\Phi_{PC} \approx \Phi_D$. For a contracting polar cap $\Phi_N >$

178   Φ_D *and* $\Phi_{PC} \approx \Phi_N$. In Figures 2b and 2c, no viscous flow excitation is included ($\Phi_V = 0$),

179   but several features often mistaken for viscous-like flows are seen in Figure 2c. In particular,

180   the convection pattern shows flow streamlines entering the polar cap over the entire dayside

181   and the transpolar voltage exceeds the dayside reconnection voltage ($\Phi_{PC} \approx \Phi_N > \Phi_D$).

182   The presence of lobe stirring cells during northward IMF, or even lobe field line re-closure by

183   reconnection at the sunward edges of both lobes (e.g. *Lockwood and Moen*, 1999), means that

184   northward IMF is inherently a non-steady-state situation because, by Faraday's law, the

185   electric field has a curl with dawn-to-dusk electric field associated with reconnection in the

186   cross-tail current sheet but dusk-to-dawn electric field along the lobe reconnection site(s) at

187   the sunward edge(s) of the lobe magnetopause (*Lockwood*, 2019). Hence during the 50% of

188   time that the IMF points northward (*Hapgood et al*., 1991; *Lockwood et al.*, 2017; 2019b) the

189   magnetosphere is quiet but also inherently in a non-steady state because of the slow decay of

190   open flux (see review by *Lockwood*, 2019).

191   Figure 3 gives two schematics of a northern hemisphere convection pattern that we would

192   expect during northward IMF; specifically, if the IMF has (a) components $B_Z > 0$ and $B_Y =$

193   0 and (b) $B_Z > 0$ and $B_Y > 0$ in the GSM reference frame. Figure 3(a) shows the case of

194   lobe reconnection (voltage Φ_L) driving symmetric lobe circulation cells in the open polar cap,

195   as well as the effects of reconnection voltages Φ_D and Φ_N and a viscous-like voltage Φ_V. In

196   Figure 3(b), the magnetic curvature force on newly-reconfigured open field lines for the large

197   positive IMF B_Y causes the dawn lobe cell to dominate: note in this case how the poleward

198   contraction of the (dusk) adiaroic open polar cap boundary causes the sunward flowing

199   portion at lower potentials of this one lobe convection cell to merge with the main dusk cell.

200   Because we here survey a very large dataset, we need to automate the scaling of transpolar

201   voltage and we found that automated algorithms to distinguish and identify lobe cells from the

202   cells driven by Φ_D , Φ_N and Φ_V were not reliable, particularly given that the merging of lobe

203   and main flow cells illustrated in Figure 3b is often seen for northward IMF conditions. To

204   enable automated scaling, we here define Φ_{PC} by

205                                     $\Phi_{PC} = \phi_{max} - \phi_{min}$ (1).

206   We apply this, irrespective of the locations at which the maximum (ϕ_{max}) and minimum

207   (ϕ_{min}) of the potential pattern occurs . This is good for investigating the ECPC model because

208   it allows for the sunward and antisunward shifts of the locations of both ϕ_{max} and ϕ_{min}

209   caused by dominant Φ_D and Φ_N, respectively (see Figures 2b and 2c). The maximum

210   potential ϕ_{max} is usually the potential at the centre of the main convention cell on the dawn

211   flank of the polar cap (ϕ_{dawn1} in Figure 3) and the ϕ_{min} is usually the potential at the centre

212   of the main cell on the dusk flank of the polar cap (ϕ_{dusk1} in Figure 3). However, if the lobe

213   reconnection voltage Φ_L is large enough, ϕ_{max} can become ϕ_{dusk2} and/or ϕ_{min} can become

214   ϕ_{dawn2}, where ϕ_{dusk2} and ϕ_{dawn2} appear across the ends of the footprint of the lobe

215   reconnection X-line and are also defined in Figure 3. Hence if $\phi_{dusk2} > \phi_{dawn1}$ and

216     $\phi_{dawn2} < \phi_{dusk1}$, our definition means that $\Phi_{PC} = \phi_{dusk2} - \phi_{dawn2} = \Phi_L$. We will call

217   Φ_{PC} in this case a "lobe-dominated" value of Φ_{PC}: note that it is a positive value even though

218   the dominant flow in the central polar cap is now sunward. If neither lobe cell sets ϕ_{min} or

219   ϕ_{max} then Φ_{PC} is the voltage associated with antisunward convection over the polar cap set

220   by Φ_D, Φ_N and Φ_V. We note below that this is the most common situation and hence we call

221   the resulting $\Phi_{PC} = \phi_{dawn1} - \phi_{dusk1}$ a "conventional" value. There is a third possibility

222   where $\phi_{dusk2} > \phi_{dawn1}$ or $\phi_{dawn2} < \phi_{dusk1}$ but not both. In either of these two cases, Φ_{PC}

223   will be somewhat larger than the conventional value and we call this a "hybrid" value as Φ_D,

224   Φ_N, Φ_V, and Φ_L can all contribute to Φ_{PC}. *Wilder et al.* (2008) have surveyed SuperDARN

225   data and shown that the lobe reconnection voltage in the ionosphere Φ_L saturates at about 15-

226   20 kV. This means that voltages above 20kV are almost all "conventional" values associated

227   with dominant antisunward transfer of flux over the polar cap and set by Φ_D, Φ_N and Φ_V.

228   However for $\Phi_{PC} < 20$kV we need to remain aware that Φ_D, Φ_N, Φ_V, and Φ_L can all

229   contribute to Φ_{PC} for the hybrid cases and that for the lobe-dominated cases $\Phi_{PC} = \Phi_L$. For

230   our definition, the viscous-like voltage Φ_V would only equal the Φ_{PC} value if all three

231   reconnection voltages Φ_D, Φ_N and Φ_L were zero.

232   *Milan et al.* (2021) surveyed one-year of data and found that roughly 20% of all antisunward

233   magnetospheric flux transfer was during quiet periods, 43% during non-steady-state phases

234   (20.8% substorm growth, 9.8% substorm expansion, 3.3% substorm recovery, 1.2% recovery

235   bays and 8% multiple intensifications). The remaining 37% was during intervals they classed

236   as "driven" – these include extended substorm growth phases and periods when dayside and

237   nightside reconnection are close to being balanced ($\Phi_D \approx \Phi_N$). This driven state was found

238   for 18.2% of the time, compared to 27.2% of the time for the non-steady phases. Together

239   these make up the 50% of time for which the IMF points southward and, as noted above,

240   northward IMF is inherently non-steady and so non-steady conditions are present 77.2% of

241   the time. Hence, in both time and resulting flux transfer, non-steady conditions are the

242   dominant magnetospheric response. However, we introduce steady state into our view of the

243   coupled magnetosphere-ionosphere system at all times if we average data together. In steady-

244   state, the rate of flux transfer across the polar cap, Φ_{PC} equals the rate at which field lines are

245   opened by reconnection in the dayside magnetopause (the dayside reconnection voltage Φ_D)

246   and the rate at which open field lines are closed by reconnection in the cross-tail current sheet

247   (the nightside reconnection voltage Φ_N), plus any non-reconnection "viscous-like"

248   voltage, Φ_V (i.e. $\Phi_{PC} = \Phi_D + \Phi_V = \Phi_N + \Phi_V$). The balanced reconnection ($\Phi_D \approx \Phi_N$)

249   needed for steady state can occur at any one moment by chance or could be the result of a

250   mechanism that maintains it. As yet, no such mechanism has been defined. Furthermore,

251   there are reasons to believe that no such mechanism can be present: for it to operate,

252   information about the magnetopause reconnection voltage at any one time Φ_D would have be

253   able to reach the nightside reconnection site so the mechanism can modulate Φ_N. Because of

254   propagation delays, at the nightside reconnection site there can be no information about the

255   instantaneous value of Φ_D at the dayside reconnection site, and so $\Phi_D \approx \Phi_N$ cannot happen as

256   a matter of course, maintained by a balancing mechanism. Faraday's law applied to the open-

257   closed field line boundary gives the general behaviour:

258 $$dF_o/dt = B_i.dA_o/dt = \Phi_D - \Phi_N \qquad\qquad (2)$$

259   where F_o is the open magnetospheric flux, A_o the area of the open field line polar cap in the

260   ionosphere and B_i is the magnitude of the field in the ionosphere (in this equation, B_i is

261   assumed to be constant). Note that Equation (2) can be thought of as the continuity equation

262   for the open flux F_o. Hence steady state requires $\Phi_D = \Phi_N$ and $dF_o/dt = dA_o/dt = 0$

263   and the fact that the polar cap area varies shows that non-steady conditions apply (*Holzer et*

264   *al.,* 1986; *Milan et al., 2003; Milan*, 2004). The results of *Lockwood et al.* (2009) and *Milan*

265   *et al.* (2021) show that non-steady state is a common situation, which is to be expected

266   because of the variability in the IMF orientation (and hence Φ_D) and the fact that the transfer

267   of information from the dayside magnetopause reconnection site to that in the cross-tail

268   current sheet takes time and hence Φ_N can only respond after a lag. How common balanced

269   convection ($\Phi_D \approx \Phi_N$) events are found to be is a matter of definition (see *McWilliams et al.*,

270   2008) and they will be less common if tighter limits are placed on the maximum ($\Phi_D - \Phi_N$)

271   used to define them. For a large averaging timescale τ, the time derivatives in equation (2)

272   tend to zero because long-term trends in F_o and A_o are negligibly small. So, for large enough τ

273     $$< \Phi_{PC} >_\tau - < \Phi_V >_\tau = < \Phi_D >_\tau = < \Phi_N >_\tau \qquad\qquad (3)$$

274   even though this condition only applies relatively rarely at any one instant of time during

275   southward IMF.

276   The voltage Φ_V is generated by any non-reconnection process transferring momentum from

277   the flow of the shocked solar wind in the magnetosheath to closed field lines (e.g., *Farrugia*

278   *et al.*, 2001).   The ECPC model predicts that Φ_V is small and that most of what had

279   previously been thought to be voltage driven by viscous-like processes is, in fact, due to the

280   nightside reconnection voltage Φ_N which always persists because the geomagnetic tail never

281   erodes away and so there is always magnetic shear in the centre of the tail (*Wygant et al.*,

282   1983, *Lockwood et al.*, 1990; *Lockwood,* 1991; *Milan*, 2004).   Numerical simulations have

283   confirmed that Φ_N contributes to transpolar voltage Φ_{PC} in addition to Φ_D (e.g., *Gordeev et*

284   *al.,* 2011).

285   *Lockwood* (1991) pointed out that a consequence of the ECPC pattern is that Φ_{PC} for a given

286   Φ_D, Φ_N and Φ_V will depend on the shape of the open polar cap and how it is changing and

287   only for an open polar cap that remains circular at all times is the voltage across the centre of

288   the polar cap equal to $\Phi_V + (\Phi_D + \Phi_N)/2$. Hence, in general, for the duration of each polar

289   cap traversal by a LEO satellite we need to consider non-steady conditions, and that each Φ_{PC}

290   value observed will depend on Φ_D, Φ_N, and Φ_V and on how the polar cap is changing shape

291   (i.e., the motion of the adiaroic boundaries which reflect the potential distribution along the

292   boundary) and, critically, on the satellite path. Some changes in the polar cap shape are an

293   integral part of the ECPC flow excitation mechanism proposed by *Cowley and Lockwood*

294   (1992), specifically the equatorward expansion around noon caused by sudden increases in

295   Φ_D and the poleward contraction around midnight caused by sudden increases in Φ_N.

296   However, other polar cap shape distortions are likely. Examples include the effects of

297   changes in the IMF B_Y component (*Lockwood, 1991; Cowley et al.*, 1991b) or transient and

298   propagating filamentary field aligned currents in Travelling Convection Vortices induced by

299   solar wind dynamic pressure pulses (e.g., *Lühr et al.*, 1996). In addition, prolonged

300   northward IMF can lead to open flux collecting towards midnight, giving a more triangular

301   open flux region characteristic of the "horse-collar" pattern in global auroral images (*Hones et*

302   *al.,* 1989; *Birn et al.,* 1991): it has been proposed that this is enhanced by lobe reconnection

303   taking place in both hemispheres which removes dayside open flux (*Milan et al.*, 2020).

304   Hence the use of a circular open polar cap in Figures 2 and 3 is illustrative only.

305   Nevertheless, in general, passes of the dayside polar cap will reflect the influence of Φ_D to a

306   greater extent and for passes over the nightside polar cap the influence of Φ_N will be greater.

307 The question then arises as to what is the minimum averaging timescale τ required to make

308 equation (3) apply to a good approximation? Clearly, τ smaller than about 3 hours is

309 inadequate as it is comparable to the timescales of the substorm cycle over which the open

310 polar cap expands and contracts (*Holzer et al.*, 1986; *Lockwood et al.,* 1990; *Lockwood and*

311 *Cowley,* 1992, *Milan et al.*, 2003; 2009; 2012; *Huang et al.*, 2009). *Imber et al.* (2013) show

312 that over the sunspot cycle the polar cap area is remarkably constant, making dF_o/dt

313 negligible over timescales τ of order years. Both modelling (e.g., *Lopez et al.,* 2001) and

314 observational studies (e.g., *Mishin and Karavaev,* 2017) show that F_o rises during the initial

315 phases of large geomagnetic storms but F_o, like Φ_{PC} (e.g., *Kubota et al.*, 2017), appears to

316 saturate establishing a temporary quasi-steady state, before falling again as the storm declines.

317 These "Balanced Reconnection Intervals" (BRI) are related to the phenomenon of "Steady

318 Magnetospheric Convection" (SMC) (*McWilliams et al.*, 2008) events but do not necessarily

319 start with a substorm growth phase nor end with a substorm expansion phase (*DeJong et al.*,

320 2008); however, because in general there is a long-term variation in F_o around both BRI and

321 SMC events (*Lockwood et al.,* 2009 ; *Milan et al.,* 2021) they cannot be considered a steady-

322 state phenomenon on timescales shorter than their duration. However, we note that some BRI

323 and SMC events probably can occur without prior, or subsequent, major change in F_o and

324 these would be chance occurrences of matched Φ_N and Φ_D variations or because the rate of

325 change in Φ_D has been slow enough for Φ_N to respond despite the propagation lag. Note also

326 that the high variability of IMF orientation, and hence power input into the magnetosphere

327 gives this a lower occurrence frequency than that non-steady conditions (*Lockwood et al.*,

328 2019b; c).

329 In general, we need τ to exceed storm durations for steady state to fully apply. *Haines et al.*

330 (2019) have surveyed geomagnetic storms in the homogeneous aa index, aa_H (*Lockwood et*

331 *al.*, 2018a; b) since 1868, defining storms as when aa_H exceeded its overall 90th percentile: of

332 the 10^4 storms defined by this threshold, none lasted more than 3 days. Hence τ ≥ 3 days

333 should generally make steady-state a valid assumption. We note that *Weigel* (2007) proposes

334 that the time constant is considerably longer than this, such that non-steady conditions and

335 solar wind history even means that the time of year influences the variation; however, as

336 demonstrated by *Lockwood et al.* (2016), this would generate an "axial-like" time-of-

337 day/time-of-year pattern and we can discount this proposal.

1-ii. SuperDARN Transpolar Voltage Data and Potential Patterns

The studies of transpolar voltage discussed in the previous section were made using observations of electric fields and plasma flows by LEO satellites as they passed over the polar caps. One problem with this is that the satellite path will not generally intersect the points of maximum and minimum potential and so the difference between them, the full transpolar voltage Φ_{PC}, will be systematically underestimated. In addition, because there is no information of the potential pattern away from the satellite path, there is no way of checking if, or by how much, any one value is an underestimate. Studies have generally used passes that are close to the dawn-dusk meridian to try to minimise this problem, but the ECPC model predicts that this will only work for steady state conditions. This is because, as illustrated by Figures 2b and 2c, for dominant magnetopause reconnection ($\Phi_D > \Phi_N$), both the maximum and minimum of the potential pattern will be shifted towards noon and for dominant tail reconnection ($\Phi_N > \Phi_D$) they are shifted towards midnight. In this paper we use values derived from the SuperDARN (Super Dual Auroral Radar Network) coherent radar arrays (see review by *Chisham et al.*, 2007). By imaging the convection pattern, the points of maximum and minimum potential can be identified and the problem inherent in the spacecraft data avoided. As discussed in Section 1-i, we adopt the definition $of\ \Phi_{PC}$ given in equation (1) and use an automated algorithm to compute it from patterns of the ionospheric potential, ϕ.

However, there are some other important points to note about the transpolar voltage data from the SuperDARN radars. The radars monitor the line-of-sight component of the flow of F-region plasma by measuring the Doppler shift of coherent echoes that have reflected off convecting ionospheric irregularities embedded in the bulk plasma flow. The most accurate method for generating two-dimensional field-perpendicular convection velocity vectors from the SuperDARN radar data is by combining the line-of-sight measurements within a common field-of-view of pairs of radars (e.g., *Greenwald et al.*, 1995). However, because of the aspect sensitivity of echoes with respect to the structures causing the scatter, for much of the time when echoes are recorded by one radar, they are not detected by the twin radar looking in a different direction and so opportunities to make these "bistatic" observations are relatively rare. Hence methods to find the functional form for the distribution of electrostatic potential ϕ that was a best fit to all the line-of-sight velocity measurements were developed (*Ruohoniemi*

369 *and Baker*, 1998; *Cousins et al.*, 2013). The most widely used of these is the "map-potential"

370 technique (a form of re-analysis using data-assimilation), which performed well when tested

371 against available bistatic vectors (*Provan et al.,* 2002). However, lack of radar coverage

372 and/or of the required scattering irregularities mean that line-of-sight data are not available at

373 all locations in the polar regions and so the velocity data are supplemented with predictions by

374 a statistical model, driven by the IMF conditions observed by an upstream monitor. From

375 each derived map-potential pattern the transpolar voltage Φ_{PC} can be scaled (*Bristow et al.*,

376 2004; *Wilder et al.*, 2011). A review of the development and application of this technique has

377 been presented by *Chisham et al.* (2007).

378 The statistical model predictions used in the map-potential technique are weighted to

379 minimize their impact for a given number of available radar echoes, n_e (*Shepherd and*

380 *Ruohoniemi*, 2000). At times there are sufficient numbers and wide enough spatial

381 distribution of echoes for the potential pattern to be determined from the radar data alone; on

382 the other hand, in extreme cases with no echoes ($n_e = 0$), the pattern is determined purely by

383 the model and hence by the observed upstream interplanetary conditions. Tests of flow

384 velocities derived using the SuperDARN radars have been made by comparing the map-

385 potential flow estimates with data from the Defense Meteorological Satellite Program, DMSP

386 (e.g., *Xu et al.,* 2007a; b; *Drayton et al.*, 2005) and Swarm (*Koustov et al.*, 2019a) spacecraft.

387 In addition, transpolar voltage data from the SuperDARN map-potential data have been

388 compared to those derived by the AMIE (Assimilative Mapping of Ionospheric

389 Electrodynamics) technique that uses a variety of sources, particularly magnetometers (*Gao*,

390 2012). Given that there is a tendency for flow speeds defined by SuperDARN to be about

391 30% lower than seen by satellites (*Xu et al.*, 2007b; *Drayton et al.,* 2005; *Koustov et al.*,

392 2019a), but that convection reversal boundary locations in the two data sets are very similar,

393 we would expect SuperDARN values of Φ_{PC} to be well correlated with the satellite values but

394 typically 30% lower. From the detailed comparison shown in part (c) of Figure A1 in

395 Appendix A, allowing for the effect of the number of data echoes n_e and the proximity of the

396 satellite pass, we find a similar result but the best fit regressions (linear and non-linear) show

397 that the radar values are typically 20% lower.

398 In this paper we use a variety of threshold values n_{min} of the number of radar echoes n_e to

399 investigate the effect of low n_e on our results. All Φ_{PC} values based on $n_e < n_{min}$ echoes

400 were discarded, and we varied n_{min} to determine the sensitivity of our results to the choice of

401 n_{min}.

402 The use of a $n_e > n_{min}$ selection criterion has an important but subtle implication for biases in

403 the data because considerably fewer echoes are received during summer. This is probably due

404 to combination of causes acting together including: sporadic E-blanketing of F-region radar

405 returns; interference from enhanced ground echoes; a smoother ionosphere when

406 photoionization rate is high and the effects of radar transmitter frequency selection (*Koustov*

407 *et al.*, 2019b and references therein). Here, we only use potential maps from the northern

408 hemisphere radar array with its greater number of stations and the means of n_e are

409 consistently about 200 around the June solstice (summer) whereas they are typically between

410 500 and 600 around the December (solstice) winter. This means that hourly values that meet,

411 for example, a $n_e > n_{min} = 255$ criterion are quite rare in summer and atypical (around 2-3

412 per day, whereas there are typically 20-24 per day in winter).

413 The other factor that we need to be aware of is that the occurrence of echoes also increases

414 with the plasma velocity (*Koustov et al.*, 2019b). This means that although we want to avoid

415 samples with low n_e to minimise the role that the data-assimilation statistical convection

416 model plays in the Φ_{PC} value, we do not want to eliminate too many samples because that

417 would preferentially remove low-flow (and hence low-Φ_{PC}) samples.

418 The ECPC model has been used quantitatively to match to map-potential SuperDARN

419 observations of the evolution of the convection pattern and Φ_{PC} following individual events

420 of southward and northward turnings of the IMF (*Lockwood et al.*, 2006), events that were

421 also quantitatively compared with the associated signatures of magnetopause reconnection in

422 cusp proton precipitation and aurora (*Lockwood et al.*, 2003; *Throp et al.,* 2005). Here we

423 make a statistical study of the Φ_{PC} data from SuperDARN using data from 25 years – more

424 than a full Hale solar magnetic cycle.

425 **2. Data Employed**

426 In this paper we make use of 214410 hourly observations of the ionospheric transpolar

427 voltage Φ_{PC}, as defined by equation (1), derived from map-potential ϕ patterns obtained by

428 the northern-hemisphere SuperDARN radar network between 1995 and 2020. These data are

429 generated by applying the map-potential technique to data from 2-minute integration periods

430 and the 30 values of Φ_{PC} and n_e in each hour were then averaged together. The processed

431 data have been checked using comparisons with dawn dusk passes by DMSP satellites from

432 2001-2002 for which the SuperDARN convection patterns show potential minima and

433 maxima close to the satellite path (see Appendix A).

434 We compare with data on the north-south component of the IMF in the GSM frame, B_Z

435 (defined positive northward), and the solar wind dynamic pressure, p_{SW}, both taken from the

436 OMNI dataset, compiled and maintained by NASA's Goddard Space Flight Center (*King and*

437 *Papitashvili,* 2005). We also compare with the AL auroral electrojet geomagnetic index

438 compiled and maintained by the World Data Centre for Geomagnetism, Kyoto. We use one-

439 minute values of B_Z, p_{SW} and AL. Because we are not sure of the precise propagation lags of

440 these parameters relative to the Φ_{PC} data we take running (boxcar) means over a timescale τ

441 which we then interpolate to the mid-point of the hour over which Φ_{PC} data are averaged,

442 minus a nominal lag δt. We repeated all studies using two values of τ, $\tau = 1\ hr$ to match the

443 averaging timescale of the Φ_{PC} data and $\tau = 15\ min.$: plots for the two were almost identical

444 and we use $\tau = 15\ min.$ in the plots shown. For IMF B_Z we use a lag $\delta t = 5\ min.$, to

445 allow for propagation across the magnetosheath to the dayside magnetopause reconnection X-

446 line and then down geomagnetic field lines to the ionosphere, because we are interested in the

447 effect of IMF B_Z on the dayside reconnection voltage Φ_D. For p_{SW} we have tried two

448 different values of δt: to search for an effect of p_{SW} on Φ_D we use $\delta t = 5\ min$ as for IMF

449 B_Z, and to search for an effect of p_{SW} on Φ_N we use $\delta t = 75\ min$ (derived below). The

450 latter effect is expected from squeezing of the near-Earth tail, as recently observed and

451 modelled by *Lockwood et al.* (2020a; b; 2021). Because of the persistence (i.e., a high and

452 broad autocorrelation function) in the p_{SW} data series, the results are similar for the two δt

453 values; however, slightly clearer effects are seen for $\delta t = 75\ min.$ and that is the value

454 employed in the plots presented here. For AL, we use $\delta t = 0$ as both AL and the Φ_N value

455 are used as an indicator of signatures in the nightside auroral ionosphere. We compute

456 $p_{SW} = m_{SW}N_{SW}V_{SW}^2$ from 1-minute values of the solar wind mean ion mass m_{SW}, number

457 density N_{SW} and speed V_{SW}; in the case of m_{SW} these are linearly interpolated from 5 min., 15

458 min or hourly observations if 1-min. values are unavailable.

459   We note that a great many papers derive propagation delays δt between solar wind features

460   and responses in the magnetosphere and ionosphere. These are not always comparable

461   because different solar wind features and different responses are considered. In addition, some

462   effects call for IMF orientation to be considered whereas others do not. In addition, the solar

463   wind speed varies and alters the δt values.   Some studies use correlations to define the peak

464   response whereas other use the timing of the first detectable response. A detailed and

465   extensive statistical study of the delay between changes in the IMF B_Y component and their

466   effect appearing in the near-Earth tail lobes and plasma sheet was presented by *Browett et al.*

467   (2017). They found optimum delays of 1 hr for southward IMF but up to 5 hr for northward

468   IMF conditions. Because these are the times for the magnetic curvature force to take effect in

469   the tail, they relate to field-aligned Alfvén wave propagation times as well as solar wind

470   propagation times and so are not directly comparable with, for example, the propagation time

471   for dynamic pressure change effects in the tail. We note that the value of $\delta t = 75\ min$ that

472   we here derive and use, is slightly longer than the $60\ min$ that *Browett et al.* (2017) derive for

473   southward IMF but much shorter than 300 min that they find sometimes derived for

474   northward IMF.

475   **3. Results**

476   **3-i. Effect of number of radar echoes, n_e**

477   Figure 4 shows the cumulative probability distribution (c.d.f.) of the number of radar echoes

478   n_e for the 214410 samples of the ionospheric transpolar voltage, Φ_{PC}. The vertical coloured

479   lines show a set of nominal values of n_{min}, which we vary from 100 (dark red) to 900

480   (mauve) in steps of 100 in our sensitivity study (i.e., $n_{min} = [100:100:900]$). These values

481   yield subsets of 137633, 85078, 52501, 32646, 20378, 12866, 8032, 4958, and 3134 samples.

482   The black dashed line is for $n_{min} = 255$ which we discuss below, and which yields 60653

483   samples, very close to 30% of the original dataset.

484   Figure 5 shows the probability distribution functions for hourly transpolar voltage, Φ_{PC},

485   selected using the condition $n_e > n_{min}$ for the values of n_{min} used in Figure 4. It can be

486   seen that the shape of the distribution varies with n_{min}, the mode value of the normalised

487   distribution getting smaller and moving to higher values. The large-value tail of the

488 distribution therefore gets relatively larger, as expected from the discussion in section 1-ii. It

489 can be seen that for $n_{min} < 300$ the effect on the distribution shape is, however, relatively

490 minor.

491 To further define an optimum value for n_{min} we have carried out a comparison with dawn-

492 dusk passes by DMSP satellites for the years 2001 and 2002 and compared the transpolar

493 voltage derived, $[\Phi_{PC}]_{DMSP}$, with the simultaneous SuperDARN map-potential estimates,

494 $[\Phi_{PC}]_{S.DARN}$. We computed the root mean square deviation, $(< \Delta\Phi_{PC}^2 >)^{1/2}$ (where $\Delta\Phi_{PC} =$

495 $[\Phi_{PC}]_{DMSP} - [\Phi_{PC}]_{S.DARN}$) as a metric of agreement. In general, we found $\Delta\Phi_{PC}$ tended to

496 be positive, consistent with the studies discussed in section 1-ii. We used the Nelder-Mead

497 search to find a minimum in $(< \Delta\Phi_{PC}^2 >)^{1/2}$ as a function of n_{min} and the maximum allowed

498 geocentric angular separation of the satellite and radar potential maxima and minima, δ. This

499 yielded an optimum n_{min} of 255 and for the optimum maximum δ of 30° . The use of $n_{min} =$

500 255 gave a peak correlation between $[\Phi_{PC}]_{DMSP}$ and $[\Phi_{PC}]_{S.DARN}$ of 0.85 with and r.m.s.

501 deviation $(< \Delta\Phi_{PC}^2 >)^{1/2} = 18.5\ kV$, compared to a correlation of 0.82 for $n_{min} = 0$, for

502 which $(< \Delta\Phi_{PC}^2 >)^{1/2} = 21.2\ kV$ (see Appendix A). Hence agreement was most improved

503 by adopting of $n_{min} = 255$ which is a value small enough not to greatly change the shape of

504 the overall distribution of $[\Phi_{PC}]_{S.DARN}$ values, as shown by Figure 5. We also used this

505 survey to calibrate the SuperDARN estimates: where comparisons are made, we here correct

506 the systematically higher values (by a factor of 20%) from the satellite observations using the

507 linear regression of the $[\Phi_{PC}]_{DMSP}$ and $[\Phi_{PC}]_{S.DARN}$ data for $n_{min} = 255$ and $\delta < 30°$ (see

508 Appendix A).

509 In sections 3-ii to 3-iv of this paper we employ the selection criterion $n_e > n_{min} = 255$

510 (which gives us 60653 samples). However, in section 3-v we return to using all the n_{min}

511 values used in Figures 4 and 5 in a sensitivity study to show that our conclusions are not

512 influenced by the value of n_{min} adopted.

513 **3-ii. Variation of Φ_{PC} with IMF B_Z and the *AL* index**

514 Figure 6 analyses the optimum propagation lags needed for this study. The black line is the

515 lag correlogram (linear correlation coefficient as a function of lag) for Φ_{PC} and the IMF $-B_Z$

516 value (in the GSM frame). The peak correlation is with Φ_{PC} lagging behind B_Z by $\delta t = 20$

517   min. This is longer than the response time for dayside magnetopause reconnection (*Etemadi*

518   *et al.,* 1988; *Todd et al*., 1988): from the propagation delay to cross the magnetosheath, this is

519   expected to be about 5 min. which is the typical response time seen in the observational

520   studies discussed in section 1-i.   The propagation of the enhancement to the centre of the

521   polar cap was modelled using the ECPC model by *Morley and Lockwood* (2005) and a value

522   of 20 minutes from the nose of the bow shock is broadly consistent with their predictions.

523   Figure 2b shows that if the nightside reconnection voltage Φ_N is small, the transpolar voltage

524   Φ_{PC} is approximately equal to Φ_D and if we also fold in a non-zero viscous voltage this

525   becomes $\Phi_{PC} \approx \Phi_D + \Phi_V$. In addition, Figure 2b shows that this voltage appears between

526   maximum and minimum potentials at points that are close to the ends of the ionospheric

527   footprint of the magnetopause reconnection X-line. In this case the response of Φ_{PC} to IMF

528   B_z would be after the short lag with which Φ_D responds (i.e., $\delta t \approx 5\ min$). The AL index is

529   expected to be a good proxy for the nightside voltage Φ_N, becoming more negative as Φ_N

530   increases. Hence a subset of the data selected for a small $-AL$ should be give Φ_{PC} values

531   dominated by Φ_D and hence showing a small response lag. For the subset of data when the AL

532   index is above 100 nT ($i.e., -AL < 100nT$), shown by the blue line in Figure 6, the observed

533   lag of Φ_{PC} lag after B_z of $\delta t = 5\ min$ is therefore consistent with the ECPC model and low

534   Φ_N.   A notable feature of all the correlograms in Figure 6, except those for Φ_{PC} and B_z (in

535   blue and black), is that the peaks are asymmetric with higher correlations at a given time after

536   the peak than for the same time before it. This shows that higher auroral activity (i.e., larger

537   negative AL) are responses over longer time constants and that time constant is variable.

538   The orange line shows that the optimum lag for the AL index after B_z is $\delta t = 35\ min$, but the

539   peak is lower and broader indicating there is considerable variability in that lag. The green

540   line gives the lag of the AL index after Φ_{PC} of $\delta t = 25\ min$, which yields a total lag of 25+20

541   = 45 min after IMF B_z which is 10 min longer than the value obtained from the direct

542   correlation between AL and IMF B_z.   The mauve line shows the correlation between Φ_{PC} and

543   solar wind dynamic pressure p_{SW} which is considerably weaker than the other correlations, as

544   expected because Φ_{PC} depends primarily on Φ_D and Φ_N which are not expected to be as

545   strongly modulated by p_{SW} as they are by B_z. However, this Φ_{PC} versus p_{SW} correlogram

546   does show a broad, weak peak with a maximum at a lag of $\delta t = 120\ min$. This suggests that

547   if p_{SW} is exerting an influence on Φ_{PC} it is mainly via a modulation of Φ_N through squeezing

548   the near-Earth cross-trail current sheet. This will be discussed further in section 3-iii. The

549   correlation between Φ_{PC} and p_{SW} was also examined for northward and southward IMF

550   conditions separately by selecting data when the B_z data simultaneous with p_{SW} was positive

551   and negative, giving the cyan and grey correlograms, respectively. For southward IMF, the

552   peak effect is soon after that of the peak response to IMF B_z and so this appears to show an

553   influence of p_{SW} on the dayside reconnection voltage Φ_D. On the other hand, the peak

554   response for northward IMF is at a lag of $\delta t = 75\ min.$ and because of the absence of large

555   Φ_D in these cases, this appears to show a response of Φ_N to increased p_{SW} in these cases (see

556   discussion by *Lockwood*, 2013). In our studies we used δt of 5, 75 and 120 min. for the

557   optimum lag between p_{SW} and terrestrial responses: because of the high persistence in the

558   p_{SW} data series the results were very similar in the three cases, and we here show values for

559   $\delta t = 75 min.$

560   A great many studies have presented scatter plots of Φ_{PC} as a function IMF B_Z (or dawn-

561   dusk interplanetary electric field $V_{SW}B_Z$, but the radial solar wind speed V_{SW} explains very

562   little of the scatter) and shown that Φ_{PC} increases approximately linearly with $-B_Z$ for B_Z <

563   0 but has approximately constant and small values for B_Z > 0. Figure 7a shows that the

564   SuperDARN dataset used here also confirms this behaviour by comparing a scatter plot of the

565   Φ_{PC} values as a function of IMF B_Z (black points) with the corresponding scatter plot from

566   the survey by of *Cowley* (1984) using data from a variety of LEO spacecraft (mauve points).

567   Note that the satellite Φ_{PC} values have been reduced by the 20% factor found from

568   comparisons with two years' passes by the DMSP satellites (see Appendix A). Because there

569   are so many samples in our study, a scatter plot loses a great deal of information because so

570   many points are plotted on top of each other. Hence in Figure 7b we color-code the fraction of

571   samples ($n/\Sigma n$, on a logarithmic scale) in bins of narrow width in both Φ_{PC} and B_Z. The

572   bins used are $\Delta B_z = 0.5 nT$ wide in IMF B_z and $\Delta \Phi_{PC} = 2\ kV$ wide in the Φ_{PC}. The plot

573   shows the features that are familiar from other plots. Two important features to note are that:

574   (1) for southward IMF there is a considerable spread in Φ_{PC} at a given B_z; and (2) for

575   northward IMF that spread decreases with increasingly positive B_z. The plot also shows that

576   Φ_{PC} values increase slightly with increasingly positive B_z which implies that the lobe

577   reconnection voltage Φ_L increasingly becomes a factor, as discussed in relation to Figure 3.

578   In the ECPC model, the spread at a given IMF B_z is expected because in non-steady state

579   both Φ_D and Φ_N contribute to Φ_{PC}. From long-term averages (for which $\Phi_{PC} = \Phi_D + \Phi_V$)

580   we know that $(\Phi_D + \Phi_V)$ varies approximately linearly with $-B_z$ for $B_z < 0$. It is also known

581   that the auroral electrojet indices AE and AL vary approximately linearly with Φ_{PC}, again

582   with considerable scatter (*Weimer et al.*, 1990). In this paper we investigate the nightside

583   auroral electrojet index AL as a proxy for the nightside voltage, Φ_N, which is consistent with

584   its use as a substorm expansion phase identifier in substorm cycles. *Lockwood et al.* (2009)

585   used satellite passes to show that, statistically, polar cap flux decayed (i.e., Φ_N is enhanced)

586   during substorm expansion phases when $-AL$ is enhanced. *Hubert et al.* (2006) and *Milan et*

587   *al.* (2009) used auroral images to also infer the loss of open flux during substorm expansion

588   phases which also implies a relationship between $-AL$ and Φ_N. The variation of Φ_N inferred

589   from time-constants by *Laundal* (2020) shows a strong variation with $-AL$, as does the

590   analysis of the polar cap boundary location by *Aikio et al.* (2013).

591   Figure 7c shows the mean AL values in the same bins as used in Figure 7b and Figure 7d

592   shows contours of these mean AL data. Note that these contours can only be fitted in areas

593   where the data are not sparse (identified by Figure 7b). It can be seen that the spread in Φ_{PC}

594   at a constant B_z is indeed associated with the spread in AL , as predicted by the ECPC model.

595   Figure 8a plots the variation of the occurrence of combinations of the AL index and IMF B_z

596   using the same bins in B_z as used in Figure 7b and 7c and bins of AL that are 10 nT wide.

597   Figure 8b shows the mean Φ_{PC} in the same bins as used in Figure 8a and Figure 8c shows the

598   fitted contours of mean Φ_{PC} from the same data. The tilt of the contours towards the diagonal

599   in 8b and 8c shows clearly that Φ_{PC} depends on both B_z and AL: at constant AL, Φ_{PC}

600   increases with increasingly negative B_z (moving horizontally to the left of the plot) but

601   importantly, Φ_{PC} also increases with increasingly negative AL at constant B_z for $B_z < 0$

602   (moving vertically up the left-hand half of the plot). Hence Φ_{PC} increases with increases in

603   both IMF $-B_z$ and $-AL$.

604   **3-iii. Evolution of Φ_{PC} during northward IMF with time since the IMF turned**

605   **northward**

606   A second scatter plot that was important verification of the ECPC model was presented in

607   Figure 6 of *Wygant et al.* (1983). The plot looked at Φ_{PC} values during northward IMF, as a

608   function of time Δt since the IMF last had a southward component. Shortly after a northward

609   turning (small Δt), *Wygant et al.* found that almost the same range in Φ_{PC} was present as had

610 been seen during the prior periods of southward IMF. However, with increased time after the

611 northward turning (larger Δt) this range decreased because the largest observed Φ_{PC} declined

612 exponentially. This decline continued until after about 10 hours only low values of Φ_{PC} were

613 seen. This behaviour is uniquely explained by the ECPC model which predicts that the larger

614 values of Φ_{PC} seen when the IMF is northward are because there is a large Φ_N (despite Φ_D

615 being small because the IMF was northward). Large Φ_N can still be present because of the

616 large open flux that had been produced in the growth phase prior to the northward turning of

617 the IMF, there being a delay before that flux is fully appended to the near-tail tail lobes by the

618 solar wind flow. The inference was that the longer the IMF remained northward, the more

619 events of higher Φ_N had depleted the open flux and so the maximum of subsequent events

620 was reduced.

621 The *Wygant et al*. plot contained only 28 datapoints, it is here reproduced in Figure 9a for the

622 29373 datapoints available from our survey for IMF $B_z > 0$ and $n_e > 255$. To evaluate the

623 time since the IMF had a southward component, we here use 6-minute boxcar running means

624 of IMF B_z to avoid periods of northward IMF being interrupted by just a brief interval of

625 southward IMF. For each northward-IMF Φ_{PC} value observed at time t_o we evaluate the time

626 at which the IMF turned northward in these 6-minute running means, t_n, and hence $\Delta t = t_o -$

627 t_n. We did also try using running means over 15 minutes and 60 minutes and Figure 9 was

628 not substantially changed other than the appropriate resolution in Δt was lowered. Again,

629 because of the large number of samples, we colour code the fraction of samples $n/\Sigma n$ (on a

630 logarithmic scale) and all panels of Figure 9 uses bins in Φ_{PC} that are 2 kV wide (as in

631 Figures 7 and 8) and in Δt that are 6 min wide. The near-exponential decay of the largest Φ_{PC}

632 found by *Wygant et al*. is clear in Figure 9a and the time constant for that decay is very

633 similar, with Φ_{PC} reduced to almost constant value by $\Delta t = 15 \ hrs$. The ECPC model

634 predicts that the larger Φ_{PC} values at a given Δt will be due to larger Φ_N and hence greater

635 $-AL$. Figure 9b confirms that this is indeed the case by color-coding the mean of $-AL$ in the

636 same bins as used in Figure 9a. *Wilder et al.* (2008) have used SuperDARN data to show

637 that the lobe reconnection voltage in the ionosphere saturates at about 15-20 kV. From this

638 we deduce that the voltages shown in Figures 9 for Δt greater than about 15 hours after the

639 IMF turned northward are consistent with the effects of lobe reconnection. On the other hand,

640 the values above 20 kV at Δt below about 10 hours (when AL is also enhanced) are not and

641 we attribute these to enhanced Φ_N.

642   Because we are belatedly reproducing the highly significant plot by *Wygant et al.* (1983), it is

643   worth making a direct comparison. This is done as two superposed scatter plots of Φ_{PC} as a

644   function of time since the IMF was last southward Δt in the top panel of Figure 10. The black

645   dots are from the present survey, the mauve dots the data of *Wygant et al.* (1983). As in

646   Figure 7, the satellite Φ_{PC} values have been reduced by the 20% found in the comparison in

647   Figure A1c of Appendix A. It can be seen that the trend inferred by *Wygant et al.* from their

648   small data set is confirmed in our large survey. The lower panel shows the contours of mean

649     $-AL$ in our survey and confirms the role of nightside reconnection invoked by the ECPC

650   model explanation of the *Wygant et al.* plot.

3-iv. Effect of solar wind dynamic pressure, p_{SW}

651

652   In this section we investigate the effect of solar wind dynamic pressure p_{SW} on the tail of the

653   magnetosphere. From Figure 6, we use p_{SW} values taken $\delta t = 75\ min$ before the

654   corresponding AL and Φ_{PC} observation to allow for a propagation lag δt through the

655   magnetosheath from the nose of the magnetosphere to sufficient distances down the tail to

656   squeeze the tail reconnection site and so modulate the tail reconnection voltage Φ_N . The

657   analysis was also carried out for $\delta t = 5\ min$ appropriate for the propagation from the nose

658   of the magnetosphere to the dayside magnetopause and $\delta t = 120\ min$ that gives the peak

659   correlation between p_{SW} and Φ_{PC}. The autocorrelation function of p_{SW} only falls to 0.5 at a

660   lag of 6 hours and because of this great persistence in the p_{SW} data series, essentially the same

661   features as shown here were observed for all three δt values used.

662   Figure 11 looks at the dependence on IMF B_z and the solar wind dynamic pressure

663   (normalised by the mean, i.e., $p_{SW}/< p_{SW} >$) of (top) the mid-latitude am geomagnetic range

664   index, (middle) the mean $-AL$ and (bottom) the mean transpolar voltage Φ_{PC}. In the left-

665   hand panels averages are given in bins that are $\Delta B_z = 0.5\ nT$ wide in IMF B_z and 0.1 wide in

666     $p_{SW}/< p_{SW} >$. The right-hand panels show fitted contours to these data and highlight the

667   gradients (but unlike the mean values contours cannot be plotted in areas where the data are

668   sparse). For all panels, values increase as we move to the left, i.e., with increasingly

669   southward IMF. This is seen at all $p_{SW}/< p_{SW} >$ values. All parameters show an increase

670   with $p_{SW}/< p_{SW} >$, at a given IMF B_z for $B_z > 0$ and for all three parameters this increase

671   decreases as the IMF becomes increasingly southward (i.e., the tilted contours become

672   progressively more vertical). For the am index we see clear increases with increasing p_{SW} at

673   all IMF B_z, although they are weaker for more strongly southward IMF. This effect of p_{SW}

674   on am has recently been identified and modelled by *Lockwood et al.* (2020a; b; 2021) as

675   being the effect of p_{SW} in squeezing the near-Earth tail. For both $-AL$ and Φ_{PC}, on the other

676   hand the contours become vertical for strongly southward IMF and the effect of enhanced

677   p_{SW} is no longer present. We infer AL and Φ_{PC} respond to increased Φ_N caused by the

678   squeezing effect of p_{SW} on the magnetic shear across near-Earth cross tail current sheet, for

679   northward IMF and for weakly southward IMF. From the studies of *Lockwood et al.* (2020a;

680   b; 2021) we believe am also responds to the enhanced energy density stored in the tail lobes

681   because of the same squeezing effect of p_{SW}. Figure 12 confirms the trends to higher values

682   at higher p_{SW} by showing the mean values, averaged over all IMF B_z, with error bars of plus

683   and minus one standard deviation: these are large because of the large variation introduced by

684   B_z. The upward trend is seen in all three parameters but noticeably the gradient of the third-

685   order polynomial fit decreases at larger p_{SW} for both AL and Φ_{PC}. The grey areas in Figure 12

686   are bounded by plus and minus 1-sigma error in the polynomial fit.

687   Figure 9c shows that the p_{SW} effect does play a role in the behaviour during northward IMF.

688   This plot is the same as 9a and 9b but shows the mean values of p_{SW} in the bins. It can be

689   seen that the larger values of Φ_{PC} at a given time since the IMF turned northward tend to be

690   at larger p_{SW}.

691   **3-v. A sensitivity study of the effects of the availability of radar echoes**

692   In the above sub-sections, all the plots shown are for the number of radar echoes $n_e > n_{min} =$

693   255. We have also generated all the plots using all of the 9 n_{min} $values$ given by the

694   coloured lines in Figure 4. The trends in all plots are the same, the main effect being to

695   change the absolute values in the means of Φ_{PC}. Figure 13 compares the variations of Φ_{PC}

696   with IMF B_Z for the thresholds n_{min} of [100:100:900] (i.e., between 100 and 900 in steps of

697   100), shown in Figure 13b with that for $n_{min} = 255$ shown in Figure 13a. In Figure 13a the

698   mean values and standard deviations are given for each B_Z bin as well as the 6th-order

699   polynomial fit (solid line). In Figure 13b only the polynomial fits are plotted to avoid

700   overplotting the multiple cases. It can be seen that the same behaviour is seen at all n_{min}

701   values, the main difference being that Φ_{PC} values are systematically higher for larger n_{min} at

702   all values of IMF B_Z. This is expected because removal of values based on low numbers of

703 echoes systematically removes low Φ_{PC} samples, as shown by Figure 5. We note that this

704 effect is seen for both northward and southward IMF samples, except for the very largest

705 (positive) B_Z when the mean Φ_{PC} is close to 25 kV, irrespective of the n_{min} used.

706 Figure 14 makes the equivalent comparisons of the average variations of Φ_{PC} for $B_Z >$

707 0 with time elapsed Δt since the IMF turned northward. Again the clear trend is to larger Φ_{PC}

708 at larger n_{min}. However, this is not true at all Δt as the effect declines in amplitude at $\Delta t >$

709 $5 hrs$ and is not seen at all at $\Delta t > 10 hrs$, such that at the largest positive B_Z all n_{min}

710 thresholds give a near constant Φ_{PC} of 15 kV.

711 We emphasise that all the plots presented in the Sections 3-ii, 3-iii and 3-iv have been

712 generated using all 9 n_{min} thresholds of n_e used in Figures 4, 5, 13 and 14. In every case the

713 form of the plot is essentially the same, the main effect being that there are fewer samples

714 available and so the plots cover smaller ranges of the parameters as noise due to lack of

715 samples becomes a greater issue in the tails of the distributions.

716 **4. Discussion and conclusions**

717 **4-i. The dependence of transpolar voltage on magnetic reconnection in both the**

718 **magnetopause and the cross-tail current sheet**

719 We have regenerated two scatter plots that formed an important basis for the space physics

720 community's understanding of magnetospheric and ionospheric convection. The plots of

721 transpolar voltage as a function of the IMF B_Z (for example, by *Reiff et al.*, 1981; *Cowley,*

722 *1984; Boyle*, 1997; *Hairston et al.*, 1998) were generated using typically less than 100

723 satellite passes. The plot by *Wygant et al.* (1983) of transpolar voltage as a function of time

724 since the IMF was last southward was generated from just 28 data points. We here increase

725 those numbers of data points by factors of over 1000 using convection patterns derived from

726 the SuperDARN array of ground-based coherent radars.

727 We have used the AL auroral electrojet index to show that the scatter in these plots is well

728 explained by the effect of the nightside voltage caused by reconnection in the cross-tail

729 current sheet, as predicted by the Expanding-Contracting Polar Cap (ECPC) model (*Cowley*

730 *and Lockwood*, 1992), and as was postulated in discussion and application of the model (e.g.,

731 *Lockwood and Cowley*, 1992; *Milan*, 2004; *Lockwood and Morley*, 2004; *Lockwood et al.*,

732 2006; *Milan et al.*, 2003; 2021). This has not been illustrated as clearly before now.

733 **4-ii. Estimates of voltage due to viscous-like interaction across the magnetopause**

734 We have demonstrated that the residual transpolar voltage after a period of southward IMF

735 decays away with time elapsed since the IMF has been northward. After about 24 hours the

736 voltage has decayed to $\Phi_{PC} \approx 15 \ kV$ and although in general Φ_{PC} values are slightly sensitive

737 to our choice of how many echoes are required (n_{min}) to yield a valid Φ_{PC} estimate, we have

738 shown that this is not true for this estimate of the residual Φ_{PC} after long (~1 day) intervals of

739 northward IMF. There are some points that should be noted about this value. From the above

740 discussion, if both Φ_N or Φ_D could be considered to be zero at these times then we get a

741 maximum estimate of the viscously-like voltage $\Phi_V < \Phi_{PC} \approx 15 \ kV$.

742 Viscously-driven flows, by definition, appear in the region of closed field lines on the flank of

743 the magnetosphere called the low-latitude boundary layer (LLBL, see Figure 1). One problem

744 is defining what are closed field lines and *Fuselier et al.* (1999) have pointed out that some of

745 the particle flux signatures traditionally used to identify closed field lines are actually best

746 explained as open field lines. *Mozer* (1984) surveyed 24 LLBL crossings and found the

747 voltage across the LLBL on one flank ranged between 0 and 16 kV, with an average of 3 kV.

748 *Mozer et al.* (1994) surveyed 41 such crossings and found an average value of 4 kV. If such a

749 voltage existed on both flanks simultaneously this implies a viscous voltage Φ_V in the range

750 0-32 kV with a mean value of 6-8 kV. These values are obtained by integrating the along-

751 track electric field seen by magnetospheric spacecraft as they pass through the LLBL.

752 *Hapgood and Lockwood* (1993) pointed out that an assumption in these measurements is that

753 the LLBL is stationary and that the satellite moves through it so that the LLBL thickness is

754 the speed of the satellite times the time it resides in the LLBL. However, in general a better

755 approximation would be that the satellite be considered stationary and the boundary moves

756 over it and that large estimates in LLBL thickness and Φ_V can arise from a boundary that

757 happens to be moving with the craft. They used plasma characteristics in the LLBL to show

758 that for some cases of apparently large viscously-driven voltage the true value was, in fact,

759 only about 3 kV on one flank: if the same applied on the other flank Φ_V would be 6 kV. In

760 theory, we should be able to use multi-spacecraft missions the pass through the LLBL to

761 resolve boundary motions and compute LLBL thickness and voltage. Such missions include

AMPTE (Active Magnetospheric Particle Tracer Explorer), Cluster, MMS (Magnetospheric Multiscale Mission) and THEMIS (Time History of Events and Macroscale Interactions during Substorms). Although we can find several examples of the use of these spacecraft to determine LLBL thickness, a literature search has not revealed any further estimates of LLBL voltage. However, we note that *Lockwood and Hapgood* (1997) did use the AMPTE-IRM and AMPTE-UKS pair to show that the analysis of *Hapgood and Lockwood* (1993) was correct.

Detailed study of convection reversals in the ionosphere near dawn and dusk indicates that sometimes the plasma motion across them exceeds the motion of the boundary, implying they are not just moving adiaroic boundaries and there is a genuinely viscous-like process at work (*Lockwood et al*, 1988; *Chen and Heelis*, 2018); however, in such cases the true boundary motion is very difficult to determine accurately and uncertainties are large making accurate determination of Φ_V by integrating along the boundary almost impossible. *Newell et al.* (1991) and *Sundberg et al.* (2008) used LEO observations of electric fields and particle precipitations to infer the voltage across the low-altitude footprint of the LLBL and find values mainly below 10 kV with a few values over 20 kV. There are two problems with this which may explain the larger estimates of Φ_V. Firstly, the identification of closed LLBL field lines from the particle precipitations is not definitive. Secondly, the ECPC model predicts that antisunward flow on closed field lines in the ionospheric projection of the LLBL can be generated by nightside reconnection and polar cap contraction because the convection reversal boundary can be shifted from the open-closed field line boundary by the conductivity distribution in the ionosphere.

From the above, a mean value of Φ_V of around $8 \, kV$ is appropriate and so the estimate of $\Phi_V \leq 15 \, kV$ derived here from Figure 14, is somewhat higher than we would expect for an average value of past estimates. However, we stress here that this is a maximum value for Φ_V because it is derived assuming $\Phi_D = 0$ and $\Phi_N = 0$ with lobe reconnection voltages lower than Φ_V. There are reasons to believe none of these assumptions is valid. Firstly, it has been shown from outward fluxes of ionospheric ion species that opening of field lines continues between the magnetic cusps at a low level even when the IMF points northward (*Chandler et al.*, 1999; *Fuselier et al*., 2000) and observations of simultaneous "double" cusps have been interpreted as subsolar reconnection continuing even though the IMF is northward and lobe reconnection is simultaneously taking place (*Lockwood and Moen*, 1999; *Pitout et al.*, 2002;

793   *Lockwood et al.*, 2003). Thus far we have only a limited number of such observations and so

794   cannot say how common this situation is. Hence, although Φ_D is small during northward

795   IMF, it may be larger than zero some or all of the time. Secondly, as pointed out by *Lockwood*

796   (2019), the tail lobes have never been seen to vanish, no matter how long the IMF remains

797   northward. This means there is always a cross-tail current sheet with magnetic shear across it

798   at which we would expect nightside reconnection to occur, even if the resulting Φ_N is small.

799   Thirdly *Wilder et al.* (2008) use SuperDARN data to show that the lobe reconnection voltages

800   in the ionosphere saturates at about 15-20 kV and hence the voltages seen at large times since

801   the IMF turned northward are likely to be caused by lobe reconnection than by viscous-like

802   interaction.

803   Our definition of Φ_{PC} means that a lobe reconnection Φ_V would, if large enough either

804   increase (the "hybrid" case) or set the value of Φ_{PC} (the lobe-dominated case) such that its

805   effect in the ionosphere exceeded Φ_V (see section 1-i). Figure 7 shows that northward IMF

806   Φ_{PC} increases up to 15kV as the IMF approaches its largest positive values which is a

807   behaviour expected of Φ_L rather than Φ_V. Hence the 15kV is consistent with being a "lobe

808   dominated" Φ_{PC} value set by lobe reconnection and not a "conventional" or "hybrid" viscous-

809   like voltage to which Φ_V could have contributed. As a consequence, we must treat 15 kV as

810   an upper limit to the average value of Φ_V and it is very likely to be considerably lower than

811   this.

812   **4-iii. The effect of dynamic pressure**

813   There are physical reasons to expect both the Φ_D and Φ_N to be increased by increased solar

814   wind dynamic pressure p_{SW}. In both cases, the compression brought about by greater p_{SW}

815   should increase the magnetic shear across the current sheet and so enhance the reconnection

816   rate. One caveat to this idea is that the nightside reconnection must be taking place at a GSM

817   X-coordinate at which the tail is still flaring (i.e., the radius increases with increasingly

818   negative X) and so the dynamic pressure can squeeze the tail lobe and so increase the lobe

819   field (*Caan et al.*, 1973) and the cross-tail current (*Lockwood*, 2013). At larger

820     $-X$ coordinates, further down the tail, the tail radius asymptotically reaches its maximum

821   value and the component of the dynamic pressure perpendicular to the magnetopause falls to

822   zero: in this case, the lobe field and magnetic shear across the cross-tail current sheet are set

823   by the static pressure in the interplanetary medium.

824 Using the *am* geomagnetic index as a proxy indicator of magnetopause reconnection, *Scurry*

825 *and Russell* (1991) inferred statistically that dayside reconnection voltage Φ_D was indeed

826 enhanced by increased p_{SW}. However much of the evidence for such an effect comes from

827 transient responses to individual events in which p_{SW} increases suddenly (e.g., *Boudouridis et*

828 *al*., 2003). The problem with these events is there will be a number of transient responses, of

829 which the effect of p_{SW} on Φ_D is one and isolating just that one effect is difficult.

830 An important effect of p_{SW} on the tail was demonstrated directly by *Karlsson et al.* (2000)

831 who showed that near-Earth tail energy content was reduced if p_{SW} decreased and that such

832 sudden decreases caused quenching of any substorm expansion that had recently begun. This

833 strongly suggests reduced p_{SW} can reduce the nightside voltage, Φ_N. Conversely, increases in

834 p_{SW} have been seen to trigger onsets of full substorm expansion phases (*Schieldge and Siscoe*,

835 1970; *Kokubun et al.*, 1977; *Yue et al.*, 2010) and have been identified as a cause of a rise in

836 Φ_N (*Boudouridis et al*., 2008b). In some cases, the rise in Φ_N has been inferred from a loss of

837 open flux as aurora expands into what appears to be open flux (*Hubert et al*., 2006a).

838 Various observational studies suggest that increases in p_{SW} cause enhanced general

839 magnetospheric convection and field-aligned current systems as well as enhanced

840 geomagnetic activity (e.g., *Lukianova*, 2003; *Lee et al*., 2004; *Hubert et al*., 2006b;

841 *Boudouridis et al*., 2008a, *Stauning & Troshichev*, 2008). This phenomenon has been

842 modelled using global MHD models of the magnetosphere as being caused by rises in both

843 Φ_D and Φ_N (*Palmroth et al*., 2004; *Ober et al.*, 2006; *Connor et al.*, 2014; *Lockwood et al.*,

844 2020b).

845 Figure 15 looks at the implications for any influence of p_{SW} on Φ_D and Φ_N of the correlations

846 between p_{SW} and the auroral electrojet indices for both northward and southward IMF. It also

847 compares the correlograms with those for p_{SW} and Φ_{PC} for northward and southward IMF

848 that were shown in Figure 6. The blue and orange and lines are for *AU* and *AL*, respectively,

849 for southward IMF ($B_Z < 0$). Both show a rapid response, although the correlation does not

850 decay away for large positive lags as quickly for *AU* as it does for *AL*. Note that correlations

851 are lower for the southward IMF data than for northward IMF (shown by the mauve and green

852 lines) because the controlling influence of IMF B_Z is much greater for southward IMF. The

853 mauve and green lines are for *AU* and *AL*, respectively and for northward IMF we see that

854 *AL* responds to p_{SW} after a long lag, consistent with the squeezing of the tail by increased p_{SW}

855   increasing Φ_N. From the peak correlation this appears to be a relatively weak effect

856   compared to the peaks for AU: however, it must be remembered that the lag for the dayside

857   effect is short and much less variable than for any effect on the nightside and so we should

858   expect a broad, but relatively low, peak for the effect on AL. Also note the peak for AU at

859   short lags for northward IMF implies that the dayside reconnection is not only enhanced by

860   increased p_{SW} when the IMF is southward, but that it may still present and enhanced by

861   p_{SW} when it is IMF is northward. *Finch et al.* (2008) and *Lockwood et al*. (2020a) found that

862   the effect of p_{SW} on mid-latitude range indices was via the nightside substorm current wedge.

863   These authors also showed the effect was associated with Φ_N and was the origin of the

864   equinoctial time-of-day/time-of-year pattern in geomagnetic activity via the effect of the

865   dipole tilt. The modelling analysis of *Lockwood et al.* (2020b) found both influence of p_{SW}

866   via both Φ_N and the energy stored in the tail lobe. The results presented here show an effect

867   of p_{SW} on Φ_{PC}, but that the effect is smaller than for am: this indicates that the effect of

868   energy stored in the tail may be a larger factor for mid-latitude range indices such as am .

869   Since submitting the present paper, an article by *Boudouridis et al.*, (2021) has been

870   published, presenting an observation and modelling case study on enhancements in

871   Φ_D and Φ_N, and hence Φ_{PC}, induced by enhanced p_{SW}. As mentioned above, the studies of

872   transient responses do not necessarily reveal the dependence of Φ_D and Φ_N , and hence Φ_{PC},

873   on p_{SW} because of other transient responses although they do show a connection. We here

874   have shown that there is a connection on a statistical basis. One potential problem is that

875   p_{SW} has many parameters in common with the power input into the magnetosphere, but

876   *Lockwood et al.* (2020a; b, 2021) have demonstrated that it has a separate and distinct

877   influence on the am mid-latitude, range geomagnetic activity index. We here have

878   demonstrated that p_{SW} has a similar influence on the nightside auroral AL index and the

879   transpolar voltage Φ_{PC}.

Figure 1. Schematic of three convection drivers in the magnetosphere and ionosphere, adapted from *Cowley* (1982) with the addition of a reconnection X-line in the cross-tail current sheet (in green, the voltage across which is Φ_N). This X-line re-closes open field lines and is included here because in the ECPC model (*Cowley and Lockwood*, 1992) it contributes to the ionospheric transpolar voltage Φ_{PC} at any one time by adding to the effect of the reconnection voltage Φ_D along the dayside magnetopause X-line (in red) which generates open field lines. The third source of Φ_{PC} is "viscous-like" momentum transfer across the magnetopause onto closed field lines that generates a total antisunward magnetic flux transfer of closed flux of voltage Φ_V in the low latitude boundary layers (LLBL).

Figure 3. Schematic illustrations of northern-hemisphere ionospheric flow streamlines (equipotentials $d\phi$ apart) during northward IMF ($B_Z > 0$) and under the influence of the three driving voltages Φ_D, Φ_N and Φ_V discussed in Figure 1, plus a lobe reconnection voltage Φ_L. Both cases are for a contracting polar cap with $\Phi_N > \Phi_D$ giving poleward motion of the adiaroic polar cap boundaries. In part (a), lobe reconnection with IMF $B_Y \approx 0$ gives two symmetric lobe circulation cells in the polar cap. Part (b) is an example of a case with large IMF $|B_Y|$, showing the effect of $B_Y > 0$ in the northern hemisphere, which yields a dominant dawn lobe cell, the sunward flow portion of which can merge with main dusk cell at the lower potentials because of the poleward contraction of the dusk adiaroic polar cap boundary. In part (a) Φ_L is close to the value of Φ_{PC} that is set by Φ_D, Φ_N and Φ_V: in terms of the potential separation $d\phi$, the schematic in part (a) is for $\Phi_N = 8d\phi$, $\Phi_D = 2d\phi$, $\Phi_L = 8d\phi$ and $\Phi_V = 2d\phi$. In part (b) $\Phi_N = 8d\phi$, $\Phi_D = 2d\phi$, $\Phi_L = 4d\phi$ and $\Phi_V = 2d\phi$.

1328
Figure 4. Cumulative probability distribution of the number of radar echoes, n_e, used in compiling the convection patterns, and hence the transpolar voltage Φ_{PC} estimates in the dataset employed here of 214410 Φ_{PC} values obtained from the SuperDARN radar array using the map-potential technique between 1995 and 2020. The vertical lines are various threshold values n_{min} used in this paper which n_e must exceed for the Φ_{PC} value obtained to be considered valid. The vertical-coloured lines are at n_{min} of [100:100:900] and the black dashed line is at 255. The condition $n_e > n_{min} = 255$ was found to be optimum in a comparison with 2-years data from satellite passes (for 2001 and 2002, see Appendix A) and which yields $N = 60653$ valid Φ_{PC} estimates which is close to 30% of all observations. The coloured thresholds are here used in a sensitivity study to understand the effect of the adopted n_{min} threshold.

Legend (within figure):
- $n_e > 100$, N = 137633
- $n_e > 200$, N = 85078
- $n_e > 300$, N = 52501
- $n_e > 400$, N = 32646
- $n_e > 500$, N = 20378
- $n_e > 600$, N = 12866
- $n_e > 700$, N = 8032
- $n_e > 800$, N = 4958
- $n_e > 900$, N = 3134

1341   **Figure 5**. Probability density functions giving the normalised distributions of the Φ_{PC} values

1342   for threshold values for the number of echoes n_e required of $n_{min} = [100{:}100{:}900]$. The

1343   resulting total number of Φ_{PC} values in the data set meeting that requirement, N, is given in

1344   each case.
Figure 6. Lag correlograms used to determine the optimum lags δt: (black) for Φ_{PC} and IMF $-B_Z$ (in the GSM frame); (blue) for Φ_{PC} and IMF $-B_Z$ (in the GSM frame) for the subset with $-AL < 100nT$; (orange) for the $-AL$ index and IMF $-B_Z$; (green) the $-AL$ index and Φ_{PC}. The mauve, grey and cyan lines are for Φ_{PC} and the solar wind dynamic pressure p_{SW}: mauve is for all data, grey for southward IMF ($B_Z < 0$) and cyan for northward IMF ($B_Z > 0$). In each case, the first parameter of the pair has been lagged with respect to the second by the lag given by the x-axis. The vertical dashed lines are at the lag δt yielding maximum r, r_p, and the values for δt and r_p are given for each case in the legend. All data are selected by the Φ_{PC} dataset for $n_e > n_{lim} = 255$ radar echoes.
1355

Figure 7. (a) Scatter plots of transpolar voltage estimates Φ_{PC} as a function of the IMF B_Z component. The black points are for the survey of SuperDARN presented here (for $n_e >$ 255) and the mauve points are from the survey of data from various spacecraft by *Cowley* (1984). (b) The fraction of samples $n/\Sigma n$ (on a logarithmic scale) in bins that are $\Delta B_z =$ $0.5nT$ wide in IMF B_z (in the GSM frame of reference) and $\Delta \Phi_{PC} = 2\ kV$ wide in the Φ_{PC}, as a function of B_z and Φ_{PC}. The IMF B_z data are 15-minute boxcar running means of 1-min. observations. (c). The mean negative AL index $-< AL >$ in the same bins as used in part (b). In both panels only Φ_{PC} values based on $n_e > 255$ radar echoes are used and bins with no samples are shaded black. Part (d) shows the same data as part (c), fitted with contour levels. Note in relation to Part (a), *Cowley* (1984) presented the data in terms of the dawn-to-dusk interplanetary electric field, $E_Y = V_{SW}B_Z$ whereas we here use an *x*-axis of $B_Z = E_Y/V_{SW}$. Also the satellite Φ_{PC} data have been scaled to the radar values using the best-fit linear regression shown in part (c) of Figure A1 in Appendix A.
1369

Figure 8. Plots on IMF B_z component and AL index axes of (a) the fraction of samples $n/\Sigma n$ (on a logarithmic scale) and (b) mean transpolar voltage $< \Phi_{PC} >$ in bins that are $\Delta B_z = 0.5 nT$ wide in IMF B_z (in the GSM frame of reference) and $\Delta AL = 10\ nT$ wide in the AL index, as a function of B_z and $-AL$. Both of B_z and AL data are 15-minute boxcar running means of 1- minute observations. Bins with no samples are shaded black. Only Φ_{PC} values based on $n_e > 255$ radar echoes are used. Part (c) shows the same data as Part (b), fitted with contour levels.
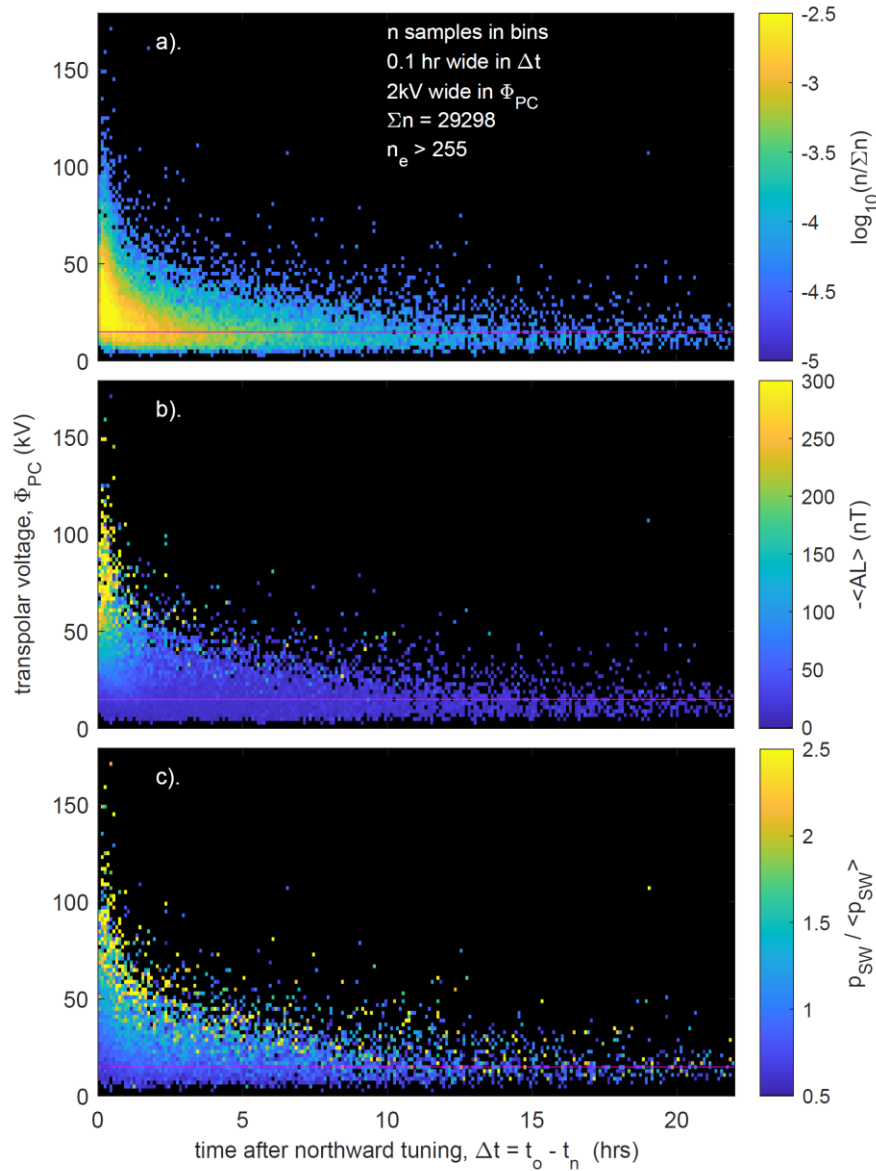

1377

Figure 9. (a) The fraction of samples $n/\Sigma n$ (on a logarithmic scale) during continuous

northward IMF ($B_z > 0$ in the GSM frame of reference, using 15-minute boxcar running

means of 1-minute IMF data) as a function of Φ_{PC} and the time that the IMF has been

northward, $\Delta t = (t_o - t_n)$, where t_o is the time of the Φ_{PC} observation and t_n is the time at

which the IMF turned northward, in bins that are $0.1 hr$ wide in Δt and $2\ kV$ wide in Φ_{PC}.

Bins with no samples are shaded black. (b) The same as (a) for the mean negative AL index

$-< AL >$. (c) The same as (a) for the normalised solar wind dynamic pressure,

$p_{SW}/< p_{SW} >$. In all there panels only Φ_{PC} values based on $n_e > 255$ radar echoes are used

and bins with no samples are shaded black.
Figure 10. Detail of Figure 9 at small times since the IMF turned northward, $\Delta t = (t_o - t_n)$, where t_o is the time of the Φ_{PC} observation and t_n is the time at which the IMF turned northward. The black dots in the top panel form a scatter plot of the Φ_{PC} data as a function of Δt from the present survey. The mauve dots are the satellite Φ_{PC} data from *Wygant et al.* (1983), which have been scaled to the radar values using the best-fit linear regression shown in part (c) of Figure A1 in Appendix A. The lower panel shows contours of the mean *AL* index for the data points of the present survey (and so is a contoured version of Figure 9b for small Δt).
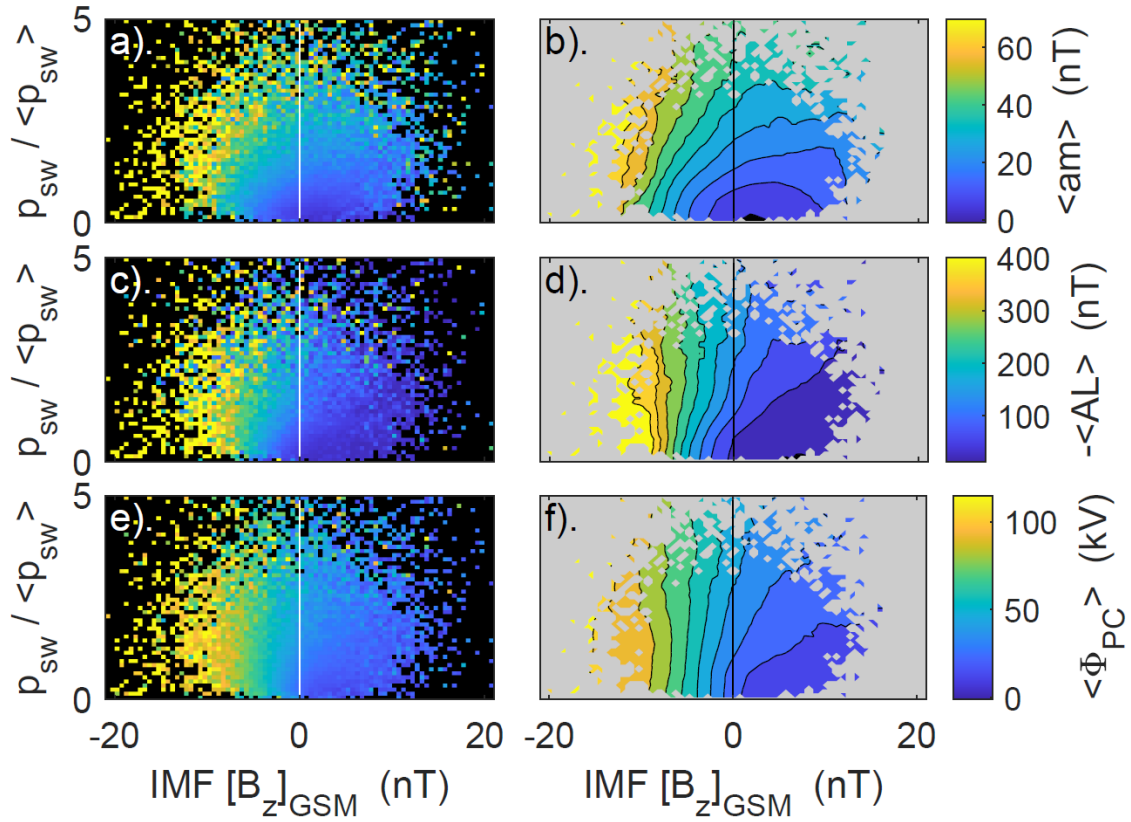

1396

Figure 11. The left-hand plots show mean values in bins and the right-hand plots the same data fitted with contours. The top plots (a) and (b) are for the mid-latitude am geomagnetic range index; the middle plots (c) and (d) are for the mean negative AL index; and the bottom plots (e) and (f) are for the mean transpolar voltage Φ_{PC}. All are as a function of the north-south IMF component (B_z, defined as positive northward) in the GSM frame of reference and the normalised solar wind dynamic pressure, $p_{SW}/< p_{SW} >$, where $p_{SW} = m_{SW} N_{SW} V_{SW}^2$ and m_{SW} is the mean ion mass, N_{SW} the number density and V_{SW} the speed of the solar wind and the normalising factor $< p_{SW} >$ is the mean for all data in the 1995-2020 period of this study. The AL, Φ_{PC}, and p_{SW} are all 15-minute boxcar running means of 1-minute data whereas the am data are linearly interpolated to the time of the Φ_{PC} sample from the raw 3-hourly am data. Bins are $\Delta B_z = 0.5nT$ wide in IMF B_z and 0.1 wide in $p_{SW}/< p_{SW} >$. Bins with no samples are shaded black in the left-hand panels and give areas of gey on the right where the data are too sparse for contours to be fitted. The am, $-AL$, and Φ_{PC} values used were for times of Φ_{PC} samples that are based on $n_e > 255$ radar echoes.
1411

Figure 12. Mean values (with uncertainty bars of plus and minus one standard deviation) of (a) the am geomagnetic range index, (b) the negative AL index and (c) the transpolar voltage Φ_{PC} as a function of the normalised solar wind dynamic pressure $p_{SW}/< p_{SW} >$ in bins that are 0.1 wide in $p_{SW}/< p_{SW} >$. The black line is the best 3rd-order polynomial fit to the mean values and the grey area around it is bound by plus and minus the 1-sigma error in the fit. The am, $-AL$, and Φ_{PC} values used were for times of Φ_{PC} samples that are based on $n_e > 255$ radar echoes.
1419

Figure 13. (a) Mean values (with uncertainty bars of plus and minus one standard deviation) of the transpolar voltage Φ_{PC} as a function of IMF B_z (in the GSM frame of reference) in bins that are $\Delta B_z = 0.5nT$ wide for Φ_{PC} samples that are based on $n_e > 255$ radar echoes. The solid line is a 6th-order polynomial fit to the mean values. (b). Analysis of the effect on part (a) of the threshold required for the number of radar echoes, n_e. The coloured lines are 6th-order polynomial fits to the mean values of Φ_{PC} for n_e thresholds of $n_{lim} = [100:100:900]$ that were also used in Figures 4 and 5.
Figure 14. (a) Mean values (with uncertainty bars of plus and minus one standard deviation) of the transpolar voltage Φ_{PC} during northward IMF as a function of time since the IMF turned northward, $\Delta t = (t_o - t_n)$ in bins that are $0.1hr$ wide: t_o is the time of the Φ_{PC} observation and t_n is the time at which the IMF turned northward. Φ_{PC} samples are based on $n_e > 255$ radar echoes. The solid line is a 6th-order polynomial fit to the mean values. (b) Analysis of the effect on part (a) of the threshold required for the number of radar echoes, n_e. The coloured lines are 6th-order polynomial fits to the mean values of Φ_{PC} for n_e thresholds of [100:100:900] that were also used in Figures 4, 5 and 13.
1436

Figure 15. Lag correlograms for auroral electrojet indices with solar wind dynamic pressure: (mauve) for AU and p_{SW} for IMF $B_Z > 0$ (in the GSM frame); (green) for AL and p_{SW} for IMF $B_Z > 0$; (blue) for AU and p_{SW} for IMF $B_Z < 0$; and (orange) for AL and p_{SW} for IMF $B_Z < 0$. In each case, the first parameter of the pair has been lagged with respect to the second by the lag given by the x-axis. The vertical dashed lines are at the lag δt yielding maximum r, r_p, and the values for δt and r_p are given for each case. The cyan and grey lines are the corresponding lag correlograms for the transpolar voltage Φ_{PC} and p_{SW} for IMF $B_Z > 0$ and IMF $B_Z < 0$, respectively.

Appendix A.

The SuperDARN data used here were processed at the Institute of Space and Atmospheric Studies, University of Saskatchewan, using the SuperDARN Radar Software Toolkit (RST) 4.3 (2019) developed and maintained by the SuperDARN Data Analysis Working Group and available from the Github URL https://zenodo.org/record/3401622#.YNuIbUwo-1k

SuperDARN Data Analysis Working Group. Participating members; Thomas, E. G.; Sterne, K. T.; Shepherd, S. G.; Kotyk, K.; Schmidt, M. T.; Ponomarenko, P. V.; Bland, E. C.; Walach, M.-T.; Reimer, A. S.; Burrell, A. G.; Billett, D. D. (2019) SuperDARN Radar Software Toolkit (RST) 4.3, doi: 10.5281/zenodo.3401622

To allow reproduction of the dataset, note that all the RST (version 4.3) defaults were used to create the potential maps, except the following:

(i) fitacf-version 3.0 was used instead of fitacf-version 2.5

(ii) -tl 60 (scan time 60 seconds)

(iii) -c (concatenate grid files)

(iv) -minrng 10 (include data from minimum range gate 10)

(v) use -cn a, b, c, d for channel fitacf files (a, b, c, d in the filename), or -cn_fic A, b for fitacfs with twofsound for channel 0 and 1 for A and channel 2 for B

(vi) -xtd for extra variable spectral width and SNR

(vii) -stime 00:00 to give start time at 00:00

(vii) -vemax 10000 to exclude any data above velocity value of 10,000 ms^{-1}

(viii) -l 50 to set map minimum latitude to 50 degrees

(ix) -if OMNI.txt to use OMNI dataset to drive re-analysis model

(x) -d 00:10 for 10 minute delay on the input OMNI data. Note that the results were not sensitive to this value and Figure 6 of the main paper shows that the observed lag between Φ_{PC} and IMF B_z is 20 min and set by the observed radar Doppler shifts and not the model.

(xi) -o 8 for harmonic order 8

(xii) -d l for low doping level. The doping level sets the relative weight given to the model compared to the data and can be set to light, medium and heavy. As we wish the maps to be strongly data-driven, we have set the model doping to light.

1474   We here present an overview plot of the comparisons between SuperDARN and DMSP

1475   transpolar voltages (respectively $[\Phi_{PC}]_{\text{S.DARN}}$ and $[\Phi_{PC}]_{\text{DMSP}}$) referred to in the text. (The full

1476   analysis will appear in the paper Lockwood, M., K.A. McWilliams, and M.R. Hairston,

1477   Semiannual and Universal Time variations in magnetospheric convection: 1. Transpolar

1478   Voltage Data, to be submitted to J. Geophys. Res.). These comparisons are for data from

1479   2001 and 2002 and are for dawn-to-dusk DMSP passes only and consider the effects of both

1480   the proximity of the satellite path the diameter of the polar cap giving the transpolar voltage in

1481   the SuperDARN data (quantified by the parameter δ_{max}) and the number of echoes, n_e

1482   involved in computing $[\Phi_{PC}]_{\text{S.DARN}}$.
Figure A1. Comparisons of simultaneous (with 30 minutes) transpolar voltage measurements by the SuperDARN radars, $[\Phi_{PC}]$S.DARN, and from DMSP satellite passes, $[\Phi_{PC}]$DMSP. The scatter plot in (a) is for all data, irrespective of how many radar Doppler shift measurements contributed to the SuperDARN values and the Magnetic Local Times (δ values) of the DMSP intersections of the convection reversal boundary (CRB). In (b) the derived stringent criterion for the MLT of the DMSP intersections of the CRB ($\delta \leq \delta_{max} = 2hrs$) has been applied. In (c) The same restriction is applied to the DMSP passes and the number of radar data points, n_e must exceed 255. On all three plots, the mauve line is the best linear regression, the green line the 2nd-order polynomial fit, and the orange dashed line the ideal agreement ($[\Phi_{PC}]$S.DARN $= [\Phi_{PC}]$DMSP). The correlation coefficient, r, and the r.m.s. deviation of the two data sets, Δ, is given in each case. The number of data points in (a), (b) and (c) are 16714, 6023 and 2468, respectively.
