10   **Key points**

11   •   Dune slipface angle adjusts to the imposed flow at time scales similar to the evolution of

12   dune height and length.

13   •   The initiation of a flow separation zone intensifies trough scour, and results in acceleration

14   of dune growth.

15   •   Sediment transport distributions reveal that bed material avalanche processes over dune

16   leesides depend on dune slipface angle.

Abstract

18   Dunes dominate the bed of sandy rivers and they respond to flow by changing shape and

19   size, modifying flow and sediment transport dynamics of rivers. Our understanding and ability

20   to predict dune adaptation, particularly dune growth and decay, remains incomplete. Here we

21   investigate dune growth from an initial flatbed in a laboratory setting by continuously mapping

22   the 3D bed topography using a line laser scanner combined with a 3D camera. High-resolution

23   profiles of flow velocity and sediment concentration providing both bedload and suspended

24   sediment fluxes were obtained by deploying Acoustic Concentration and Velocity Profiler

25   technology. Our analysis reveals that the magnitude of the dune slipface angle, which determines

26   flow separation and controls turbulence production, adjusts to the imposed flow at time scales

27   similar to the evolution of dune height and length. The initiation of a flow separation zone

28   intensifies through scour, and results in acceleration of the dune growth. Gradients in sediment

29   transport and the rate of dune growth are inherently linked to spatial variations in slipface angles.

30   During dune growth, the slipface angle evolves differently than the ratio of dune height to length,

31   which immediately reaches its equilibrium value after dune initiation.

1 Introduction

Interaction between a flow field and the underlying sandy bed gives rise to bedform topography at a wide range of spatial and temporal scales. Dunes are the most common and prominent bedforms observed in sandy alluvial systems. They are an important source of flow resistance, generating macroturbulent coherent structures that lead to enhanced dissipation of flow kinetic energy at viscous microscales (e.g., Venditti & Bennet, 2000). In addition, dune development, migration and growth dominate sediment transport dynamics in sand-bedded rivers (Gomez et al., 1990; Venditti et al., 2005a; Frings and Kleinhans, 2008; Ma et al., 2017). Dune migration also leaves a characteristic signature in the rock record – cross stratification – a key building block of alluvial deposits on Earth as well as on other planets (e.g., Ewing et al., 2015; Galeazzi et al., 2018; Best & Fielding, 2019; Leary and Ganti, 2020). Hence, dunes have attracted substantial attention from geomorphologists, sedimentologists, and hydraulic engineers with a rich history of observations from Sorby (1859) and Gilbert (1914) until today.

Research on dunes have considered dune initiation from a flatbed and growth towards a dynamic equilibrium state in steady uniform flows. Theories that explain dune initiation include the generation of bed defects by coherent turbulent flow structures that grow by downstream propagation (e.g., Grass, 1970; Williams and Kemp, 1971; Gyr and Schmidt, 1989; Best, 1992) and instability interface theory that suggests instantaneous generation of bedforms due to an instability formed at the water-sediment interface (Liu, 1957; Venditti et al., 2006). Defect initiation occurs near the threshold of motion for a sand bed while instantaneous initiation occurs when a general motion of a sand bed occurs (Venditti et al, 2005b). Once initiated, dune growth has been explained by invoking hydrodynamic or kinematic processes (Venditti and Bradley, 2020). Gradual dune growth by hydrodynamic processes has been explained with linear stability

analysis that involves imposing a spatial lag φ between sediment transport maximum and topographic maximum, allowing growth or diminution of initial bed perturbation (e.g., Smith, 1970; Kennedy, 1963; Fredsøe, 1981; Colombini & Stocchino, 2008). Rapid growth by kinematic processes occurs by bedform coalescence to form larger features (Raudkivi and Witte, 1990; Coleman and Melville, 1994; Martin and Jerolmack, 2013; Myrow et al., 2018; Leary and Ganti, 2020). Smaller bedforms merge or amalgamate of smaller, faster migrating bedforms to form larger, slower migrating dunes.

While existing initiation and growth theories explain how bedforms initiate and grow, they provide little insight into bedform morphology (shape and dimensions) and kinematics (translation and deformation) during growth. Recently, Bradley and Venditti (2019a) used large-scale flume experiments that covered a wide range of flow and sediment transport conditions to show that the process of dune growth from an initial flatbed is more complex than previously conceptualized, and that the functional form of dune growth curves – depicting spatially-averaged time evolution of dune height and length – strongly depend on the transport stage applied. In particular, a punctuated growth curve was found for mixed load dominated conditions, with an initial slow linear growth of bedforms followed by a period of exponential growth. The initial growth was attributed to organization of small 2D features which gradually grew into 3D features. It was further suggested that the successive exponential growth phase may be a result of increased trough scour due to enhanced turbulence at the bed caused by flow separation behind dune leesides. Although growth curves are prevailing tools that allow prediction of dune dimensions and their response to imposed flows, particularly of importance through passage of a flood wave, their explanatory power of underlying dune growth mechanisms remains limited.

78   Understanding dune growth requires consideration of turbulent flow fields, dune

79   morphology, sediment transport, and the redistribution of sediment over and among dunes,

80   details of which are not captured by mean geometric parameters such as dune height and length

81   (Parsons and Best, 2013; Reesink et al., 2018). Significant progress has been made into

82   understanding the dynamics of flow separation and eddy generation over fixed and mobile, high-

83   angle dunes (HADs) (e.g. Omidyeganeh and Piomelli, 2013; Naqshband et al., 2014b, 2017;

84   Bourgoin et al., 2020; Dey et al., 2020) and low-angle dunes (LADs) (e.g., Best and Kostaschuk,

85   2002; Motamedi et al., 2012; 2014; Kwoll et al., 2017; Unsworth et al., 2018; Lefebvre et al.,

86   2016; 2019). Yet quantitative observations and simulations of sediment fluxes along migrating

87   and changing dune forms remain extremely rare (Naqshband et al. 2014b, 2014c, 2017).

88   Consequently, we lack insight into sediment erosional and depositional processes causing dune

89   adaptation (changes in dune morphology and kinematics) to imposed flows. More specifically,

90   there is no mechanistic explanation of how changes in a turbulent flow field associated with

91   changes in dune morphology – most notably dune slipface slope (steepest segment of dune

92   leeside) – result in sediment transport gradients along dune beds, and how this spatiotemporal

93   variation in sediment flux contributes to dune growth.

94   Here we investigate dune growth from an initial flatbed in a shallow laboratory flume by

95   continuously mapping 3D bed topography as it evolved towards a dynamic equilibrium. High-

96   resolution sediment flux profiles referenced to the exact measured position of the bed were

97   obtained by deploying an advanced hydroacoustic flow instrumentation known as the Acoustic

98   Concentration and Velocity Profiler (ACVP). Our analysis demonstrates how sediment transport

99   gradients and the rate of dune growth are associated with spatial variation in dune slipface

100   angles, paving the way for understanding and predicting of form-related components of shear

101   stress and flow resistance, and ultimately river morphodynamics. We show that the dune slipface

102   angle progresses similarly to dune height during dune growth, as opposed to the dune steepness,

103   which reaches its equilibrium value immediately after initiation.

104   **2 Methods and Experimental conditions**

105   Experiments were carried out at the Kraijenhoff van de Leur laboratory for Water and

106   Sediment Dynamics, Wageningen University & Research. A 1.2 m wide and 14.4 m long flume

107   was used, focussing on an effective measuring section of 4 m. The slope of the flume can be

108   accurately adjusted up to 4% (Figure 1). Both water and sediment were recirculated, with a fine-

109   meshed filter mounted at the downstream end of the flume, guaranteeing full recirculation of the

110   mobile sediment load. Our experimental design, procedure, and instrumentation are briefly

111   outlined below. For more specific details of our methodology and experimental techniques see

112   Naqshband et al. (2017), and Naqshband and Hoitink (2020).

113   To investigate dune growth and adaptation, a 15-cm thick layer of uniformly distributed,

114   light-weight polystyrene particles was installed as a surrogate for sand after Naqshband and

115   Hoitink (2020). This allowed dynamic similarity of both flow characteristics (Froude number)

116   and sediment transport conditions (Shields number) between our shallow laboratory flows and

117   rivers that are an order of magnitude deeper. The bed was flattened and the flume was slowly

118   filled with water from both the upstream and downstream ends, preventing significant bed

119   disturbance. A predefined flow discharge, flume slope and water depth were chosen to represent

120   a mixed load dominated (MLD) transport condition (Table 1), with both bedload and suspended

121   load transport. The water surface slope adjusted to the imposed mean bed slope while reaching a

122   dynamic equilibrium in which dunes were not systematically growing or shrinking. Flow

123 discharge was continuously measured with an electromagnetic flow meter, and water levels were

124 monitored at four positions using evenly spaced stilling wells along the centreline of the flume.

125 The effective measurement section of the flume bed (x = 4 m to x = 8 m) was continuously

126 scanned along a 0.51 m centre strip (y = 0.35 m to y = 0.86 m) with a streamwise resolution of 2

127 mm and a crosswise resolution of 3 mm, over a period of approximately 8 hours with an average

128 time interval of 12.5 min between consecutive scans. This continuous bed level monitoring was

129 carried out using a line laser scanner combined with a 3D camera using the methods in de

130 Ruijsscher et al. (2018). As the line laser scanner is not submerged in water, bed elevation is

131 measured without disturbing the flow field and underlying bed morphology. Each bed scan

132 consists of 167 evenly spaced parallel transects over the 0.51 m wide strip. Distribution of

133 bedform dimensions (dune height Δ, length λ, and slipface angle α) were obtained from these

134 transects using a frequently applied bedform tracking tool (van der Mark et al., 2008). The

135 outlined experimental procedure was repeated to investigate the reproducibility of these

136 experiments, and to quantify the spatiotemporal variation of dune dimensions during dune

137 growth from an initial flatbed.

138 In a successive experiment under the exact same flow and sediment condition, sediment

139 flux profiles were measured over the entire flow depth, over a period of 125 min (time needed to

140 reach a dynamic equilibrium starting from an initial flatbed, T_e [min] in Table 1). Direct

141 sediment flux profiles in horizontal and vertical directions were obtained using the ACVP as

142 described by Hurther et al. (2011). It provides quasi-instantaneous, simultaneous, and colocated

143 vertical profiles of the two-component velocity field (streamwise u and vertical w) together with

144 the acoustic intensity profiles referenced to the exact location of the undisturbed bed level (using

145 the Acoustic Bed Interface Tracking method of Hurther and Thorne 2011), with a spatial and

146 temporal resolution of 1.5 mm and 1/70 s, respectively. The acoustic intensity profiles are

147 transformed into sediment mass concentration profiles applying inversion methods and

148 incoherent scattering theory to polystyrene particles (Hurther et al., 2011; Thorne and Hurther,

149 2014). Measured sediment flux profiles are further decomposed into turbulent and mean

150 contributions for both bedload and suspended load (Naqshband at al., 2014c, 2017; Fromant et

151 al., 2019). The ACVP was mounted on a measurement carriage and positioned at a fixed location

152 along the flume (x = 6 m, see Figure 1d) with dunes migrating underneath. ACVP data presented

153 herein are time-averaged over a period of 10 s in which bed displacement was negligible

154 compared to dune length. An equivalent distance is also shown which is derived by transforming

155 ACVP measurement time series into streamwise distance along the flume, using mean bed

156 displacement.

157 The ACVP technology was previously used to investigate the contribution of both

158 bedload and suspended load to migrating sand dunes in equilibrium (Naqshband et al., 2014b), to

159 quantify sediment transport distribution during dune transition to upper stage plane bed

160 (Naqshband et al., 2017), and to study boundary layer flow and sediment transport dynamics

161 under gravity current- and wave-driven sheet flows (Revil-baudard et al. 2015; 2016, Fromant et

162 al. 2018; 2019). In the present study, we deploy the ACVP to investigate dynamics of flow

163 separation in the dune leeside and associated sediment transport gradients during dune growth

164 from an initial flatbed. This will provide quantitative knowledge of the mechanisms governing

165 dune adaptation and will facilitate more accurate predictions of form-related components of

166 shear stress and flow resistance, which are crucial components in modelling sediment transport

167 and river morphology.

3 Results

3.1. Dune Growth from an Initial Flatbed

Measured bed topography illustrates successive stages of dune development and growth towards a dynamic equilibrium (Figure 2). Small bedforms instantaneously appeared over the entire bed as soon as water flow began (Figure 2a). The initial growth phase is characterised by 3D irregular features (Figure 2b) that grew and merged into larger 2D bedforms (Figure 2c). Superimposed bedforms were also observed on dune stoss slopes, causing additional events of dune splitting and merging, observed in previous research (Carling et al., 2000; Venditti et al., 2005a; Venditti et al, 2016; Reesink et al., 2018; Leary and Ganti, 2020). Soon after, however, bedform spurs (ridges parallel to the mean flow direction, Figure 2c) appeared, transforming dune crestlines back to 3D (Swanson et al., 2017). During the second, more rapid dune growth phase, dunes became higher and longer with deeper scours in their troughs (Figure 2d). Trough scouring continued during the final growth stage reaching a dynamic equilibrium.

Dune growth curves show initial linear growth followed by a period of exponential growth after $t/T_e = 0.35$ (red circle in Figure 3). Topographic variability in dune height (mean ± standard deviation) increased during the growth stage but decreased and remained constant after reaching a dynamic equilibrium (Figure 3a). Dune lengths had larger and fairly constant relative variability over the entire duration of the experiment as in previous research (Naqshband et al., 2014a; Venditti et al., 2016). Dune steepness varied through time, but showed no systematic change as the dunes grew (Figure 3c).Time evolution of spatially-averaged dune slipface angles had a rapid initial increase followed by a more gradual increase towards equilibrium (Figure 3d). Variability in dune slipface angles remained large after reaching equilibrium. Ultimately, the evolution of dune slipface angles revealed that as the onset angle for initiation of flow separation

191 (predicted to equal 11° by Lefebvre and Winter, 2016) is exceeded (red circle in Figure 3d) and

192 trough scour is intensified, less sediment bypasses the flow reattachment point, consequently,

193 more sediment arriving at the dune crest is maintained within the dune, accelerating its growth.

194 Dune slipface angle distributions change during dune growth towards dynamic equilibrium

195 (Figure 4). During the initial stage of dune development, distributions are positively skewed

196 towards lower slipface angles with mean values deviating from the corresponding modes (Figure

197 4a and 4b). In the equilibrium phase distributions are near Gaussian (Figure 4c and 4d).

198 3.2. Flow Field, Sediment Concentration, and Sediment Flux

199 Measured flow fields over growing dunes reveal distinct flow patterns caused by

200 topographic forcing (Figure 5). During the initial growth stage with relatively small dunes and

201 low slipface angles, the flow pattern is characterised by a strong downslope near-bed current and

202 gentle vertical gradients, with a maximum flow velocity over the dune trough. Recent work by

203 Kostaschuk and Venditti (2019) showed that a strong downslope current over dune leeside is

204 associated with LADs, and that these currents transport large amounts of sediment ultimately

205 contributing to the generation of small-scale, migrating, superimposed bedforms on dune

206 leesides. As dunes grow in size and their slipface angles increase, the downslope current

207 decreases in strength and a zone of flow separation starts to develop with reversed near-bed flow,

208 vertical gradients become more distinct, and the location of maximum flow velocity shifts

209 upstream towards the dune crest. In the second stage of dune growth towards equilibrium, a

210 shear layer developed and the flow separation zone further expanded, with more pronounced

211 negative near-bed velocities (e.g., Naqshband et al., 2014b; Kwoll et al., 2016).

212 The evolution of the flow field results in a characteristic sediment concentration pattern

213 over the dune bed (Figure 6a), with sediment concentration just above the undisturbed bed level

214   (detected with the ABIT method of Hurther and Thorne, 2011) equal to the granular bed density

215    $\rho_s(1 - \epsilon) = 633 \, [kg \, m^{-3}]$ ($\rho_s = 1055 \, [kg \, m^{-3}]$ is sediment density, and $\epsilon = 0.4 \, [-]$ is

216   granular bed porosity). The highest concentrations are observed close to the bed, with peaks in

217   suspended sediment over the dune stoss, at the dune crest, and over the dune leeside during the

218   initial growth phase. With initiation and expansion of flow separation in the second stage of dune

219   growth, peaks in suspended sediment concentration were observed over the dune trough due to

220   flow deceleration and the associated turbulence production, with smaller suspension peaks

221   caused by turbulent bursts that result from shear layer vortices impacting the dune bed at $t/T_e =$

222   0.92.

223   The product of flow velocity and sediment concentration gives the sediment flux (i.e.

224   mean streamwise $\overline{cu}$ and mean vertical $\overline{cw}$ sediment fluxes in Figures 6b and 6c, respectively).

225   Gradients in those fluxes ultimately drive local changes in dune morphology and dune

226   interaction. During the initial growth stage, with relatively small dunes and low slipface angles,

227   the largest streamwise fluxes are encountered at the dune crest and over the dune leeside. As

228   dunes evolve and become larger towards equilibrium, with increased slipface angles, $\overline{cu}$

229   decreases over the dune leesides and eventually becomes negative due to flow separation and the

230   upslope current. Larger slipface angles are associated with weaker downslope near-bed currents

231   (Best and Kostaschuk, 2002; Kwoll et al., 2016, 2017; Kostaschuk and Venditti, 2019), which

232   results in less pronounced (negative) downward vertical flux $\overline{cw}$ over dune leesides. The

233   observed pattern in $\overline{cu}$ further reveals a discontinuity over the dune trough at $t/T_e = 0.55$, which

234   corresponds to the location of the flow reattachment point with zero net sediment flux.

235   3.3. Sediment Transport Dynamics

236   Integration of mean streamwise flux profiles over the entire flow depth H gives the

237   distribution of total sediment transport per unit channel width along the migrating dune bed

238   (Figure 7a). Although sediment transport is usually considered as a steady flux calculated using

239   reach-averaged flow conditions, it is clear that sediment fluxes vary with topography. Bedload

240   (Figure 7b) varies with topography more than suspended load (Figure 7c). As such, bedload

241   variation controls the depth-integrated sediment flux. Consequently, dune morphology (shape

242   and dimensions) is set by bedload fluxes under the considered transport stage. The combination

243   of small dunes that possess low slipface angles associated with a strong downslope near-bed

244   current, and high sediment concentration over their crest and leeside, results in the largest

245   sediment transport rates observed during the initial stage of dune growth. As dunes grow in size

246   and their slipface angles increase, the contribution of form related flow resistance becomes

247   larger, reducing sediment transport capacity of the flow (e.g., Kwoll et al., 2017; Lefebvre et al.,

248   2016; Ma et al., 2017). This is reflected in a decrease of both dune-averaged as well as dune-

249   maximum sediment transport rates over the course of dune growth.

250   The sediment transport distribution further illustrates distinct avalanching processes of

251   bed material over dune leesides. In the presence of a flow separation zone associated with steep

252   slipface angles, avalanching is characterized by an immediate decay of bedload transport over

253   the dune leeside, reaching zero transport just ahead of the flow reattachment point. In absence of

254   a flow separation zone throughout the initial stage of dune growth, avalanching is more gradual,

255   with sediment being deposited over dune leesides and much further into dune troughs.

4 Discussion

4.1. Dune Slipface Angle and Flow Separation

Existing dune growth curves exclusively consider time evolution of dune height and length from an initial flatbed towards a fully developed equilibrium dune field (e.g., Nikora and Hicks, 1997; Iseya, 1984; Baas, 1999; Colombini & Stocchino, 2008; Coleman et al., 2005; Venditti et al., 2005a; Bradley and Venditti, 2019a). Dune slipface angles – determinative for flow separation and turbulence production – are often assumed to instantaneously reach high angles sloping at the angle-of-repose (~30°). Our experimental study with light-weight polystyrene grains allow for dune morphodynamic similarity between shallow laboratory flow conditions and rivers that are an order of magnitude deeper (Naqshband and Hoitink, 2020). We show that dune slipface angles adjust to the imposed flow at time scales similar to the evolution of dune height and length (Figure 3d). Although HADs with steep slipfaces at the angle-of-repose that produce a permanent zone of flow separation are characteristic for shallow laboratory flows, such steep slipface angles are an exception for our shallow flow dunes, analogous to observed slipface angles of dunes in deeper rivers (e.g. McLean and Smith, 1979; Kostaschuk and Villard, 1996; Galeazzi et al., 2018; Cisneros et al., 2020).

Using high-resolution numerical modelling, Lefebvre (2019) showed that the size of the flow separation zone and magnitude of reversed flow, in addition to the magnitude of the slipface angle, is controlled by slipface orientation relative to the mean flow direction. For a slipface orientation > 25° compared to the flow, a strong cross-stream current develops, suppressing turbulence and reversed flow. Previous work has also shown that sediment is dispersed in the cross-stream direction in the presence of dunes, which become more pronounced when dunes have a 3D character (Allen, 1982; Parsons et al., 2005; Reesink et al., 2018). By quantifying

279 particle hop distance and travel time over equilibrium mobile dunes, Ashley et al. (2020) showed

280 that dunes significantly increase mean and standard deviation of cross-stream hop distances

281 relative to a flatbed. Although flow and sediment data in our study is limited to 2D slices through

282 dunes which possess a 3D character from time to time (Figure 2), the analysis and insights

283 presented herein provide a basis for our understanding of dune morphodynamics, with important

284 implications for the way we consider dune morphology and its adaptation to imposed flows, flow

285 resistance and sediment transport over dunes.

286 4.2. Mechanisms of Dune Growth

287 The evolution of a bedform field from a flatbed has been shown to display exponential

288 growth at lower transport stages (e.g., Baas et al., 1999; Bradley & Venditti, 2019a; Venditti et

289 al., 2005a) and punctuated growth, when a period of initially linear growth is abruptly

290 interrupted by exponential growth, at higher transport stages (Bradley & Venditti, 2019a).

291 Exponential growth is expressed as

292
$$\Delta = a_\Delta(1 - e^{-b_\Delta * t}),$$
(1a)

293
$$\Lambda = a_\Lambda(1 - e^{-b_\Lambda * t})$$
(1b)

294 where a_Δ and a_Λ are asymptotes that describe equilibrium height and length, respectively, and b_Δ

295 and b_Λ are growth constants. The dune height and length growth curves observed in these

296 experiments (Figures 8a and 8b) show punctuated growth. Growth curves are marked by a linear

297 phase of relatively slower growth as bedforms initially evolve from the flatbed until they reach a

298 height where exponential growth occurs. In our experiments, the linear growth phase is

299   interrupted by exponential growth when t/T_e = 0.35 (Figure 3). Exponential model fit results

300   (Table 2) show that dune height reaches equilibrium slightly faster than dune length.

301   Bradley and Venditti (2019a) argued that the linear phase of growth is punctuated

302   because there is a shift in the mode of sediment transport. During the linear phase, nascent

303   bedforms grow to exceed a critical height where they can no longer be contained in the near-bed

304   flow layer. Growth then shifts to exponential as intense scour in troughs leads to more rapid

305   bedform growth. These morphodynamics are likely responsible for the height and length growth

306   curves observed in Figure 8. The Bradley and Venditti (2019a) observation of punctuated growth

307   were limited to flow depths < 0.20 m and θ/θ_C conditions up to < 21.2. Beyond this transport

308   stage, growth appeared instantaneous because it happened too quickly so that it was difficult to

309   confirm the form of the growth curves. These observations at a flow depth of 0.25 m with lower

310   density material, suggests that punctuated growth occurs at a higher transport stage (θ/θ_C = 47.8,

311   see Table 1) than observed by Bradley and Venditti (2019a).

312   The slipface angle growth curve shows purely exponential growth without an initial

313   linear phase expressed as

314                          $$\alpha = a_\alpha(1 - e^{-b_\alpha*t})$$ (1c)

315   where a_α describes the equilibrium slipface angle and b_α is a growth constant. The slipface

316   angle evolution to equilibrium lags behind dune height and length (Table 2).

317   Explaining dune growth by hydrodynamic processes requires imposing a spatial lag

318   between sediment transport maximum and topographic maximum, yet, demonstration that the

319   physical lags are real has proven challenging (c.f. McLean, 1990; Venditti, 2013). Smith (1970)

320   argued that if maximum sediment transport is located upstream of dune crest, then sediment

321 deposition will occur on the dune crest and dunes will grow larger. If the sediment transport

322 maximum is downstream of dune crest, then the dune crest will erode resulting in dune decay.

323 And, if sediment transport maximum is in-phase with the topographic maximum, dunes will

324 migrate downstream without changing shape and dimension. The measured sediment transport

325 distribution over dunes in the present study reveals – for the first time – an upstream spatial lag

326 between dune crest and maximum sediment transport which appears to vary significantly with

327 evolution phases (Figure 7a). This lag becomes more pronounced as the onset angle for initiation

328 of flow separation is exceeded during the second stage of dune growth, with sediment being

329 eroded from the dune stoss, and deposited on dune crest and leeside, resulting in dune growth.

330 Closer to equilibrium, as bedform dimensions start to stabilize, the lag disappears and the

331 sediment flux maximum coincides with the topographic maximum. Future research should

332 address the detailed causes of variability in the observed spatial lag, to provide a better basis for

333 its use in numerical bedform evolution models (e.g., Giri and Shimizu, 2006; Nelson et al., 2008;

334 Shimizu et al., 2009; Naqshband et al., 2016; Van Duin et al., 2017).

335   4.3. Low-angle Dune Formation

336   The rapid decay in bedload transport rates over the dune leesides necessarily leads to

337 oversteepening of the upper slope and avalanching on the slipface. Slipface angles in this study

338 can be compared to the two types of avalanching processes proposed by Kostaschuk and Venditti

339 (2019) to explain why deep (>2.5 m) rivers have low-angle dunes on their beds. Theoretical and

340 experimental analysis has indicated that granular avalanches composed of sand are unlikely to

341 flow on gradients <24° (Cassar et al., 2005). Kostaschuk and Venditti (2019) use this criterion to

342 separate small high-angle dunes found in flumes and shallow rivers from larger, low-angle dunes

343 in deeper flows. Low-angle slipfaces <24° are maintained by a combination of liquefied

344   avalanches capable of transporting sediment over longer distances and at lower angles than

345   granular avalanches, and downslope currents that transport bedload over the leeside when flow

346   separation becomes intermittent or absent. Mean slipface angles for the dunes in this study

347   increase from around 2° to 18° during the initial stage of dune growth to around 19.8° for

348   equilibrium dunes (Fig. 3d, Table 1). Extremes above the mean reach 27° for equilibrium dune

349   slipfaces, but most are below 24°, making them low-angle dunes.

350   Application of the Wallis-Lowe liquefaction model (see Kostaschuk and Venditti, 2019

351   for details) allows us to determine if the low lee angles are maintained by liquefied avalanches.

352   The model assumes that, at the instant of liquefaction in a deposit, the particles are supported by

353   excess pore pressure and the fractional particle concentration (volume of sediment/total volume)

354   of the dispersion is constant with a concentration C_0. As pore pressures decline, the particles

355   settle to the bed in a simple two-layer resedimentation process where the interface between the

356   dispersed grains at C_0 and the resedimentated grains, at a higher concentration C_1, rises at a

357   uniform velocity. Resedimentation is complete when the interface between the overlying clear

358   water and the liquefied dispersion coincides with the surface of the resedimented grains.

359   Complete resedimentation of the dispersion occurs over a time t_r:

360
$$t_r = \frac{\zeta(C_1 - C_0)}{C_1 \, w_d \, \cos\alpha} \qquad (3)$$

361   where ζ is the initial thickness of the deposit, α is slipface angle, $w_d = w_f(1 - C_0)^n$ is the

362   aggregate fall velocity of the dispersion, w_f is the fall velocity of a single particle, and n is an

363   empirically derived coefficient. For the simplest case of laminar flow and no interaction between

364   the liquefied grains, the maximum distance travelled by the flow is $\Gamma = t_r u_h$, where $u_h =$

365     $0.7\sqrt{(\delta\rho_{l-f}/\rho_l)g\Upsilon}$ is the slope-parallel velocity of the head of the flow, ρ_{l-f} is the density

366　　difference between the liquefied avalanche ρ_l and the overlying fluid ρ_f, and Υ is the thickness

367　　of the head. We assume characteristic values (see Lowe, 1976: cgs units are used herein to

368　　maintain consistency with empirical constants in the model) of $C_0 = 0.54$, $C_1 = 0.6$, $n = 4.7$ and g

369　　$= 981$ cm s^{-2}. The settling velocity for the polystyrene particles is measured as $w_f = 2.9$ cm s^{-1}

370　　(Table 1). Application of the model requires an estimate of the initial thickness of the triangular

371　　wedge deposit. Flume experiments have shown that slipface avalanches result from the failure of

372　　triangular-shaped wedges at the top of the slipface that are 10-20% of dune height (e.g., Venditti

373　　et al., 2005b; Reesink and Bridge, 2007). Following Kostaschuk and Venditti (2019), we assume

374　　a rectangular deposit thickness of 5-10% of dune height (1/2 the maximum triangular wedge

375　　thickness).

376　　　　Kostaschuk and Venditti (2019) calculated values of $\Gamma/S_l = 0.29\text{-}0.83$ (S_l is slipface

377　　length) for a small high-angle sand dune comparable in size to the equilibrium dunes in this

378　　study, 0.59-1.51 for a large low-angle dune in the rock record (Røe, 1987) and 0.55-1.46 for a

379　　large low-angle dune in the Fraser River. When $\Gamma/S_l > 1$, liquefied avalanches can travel the

380　　whole length of the slipface and therefore exert a first order control on the slipface angle. When

381　　$\Gamma/S_l < 1$, liquefied flows would be confined to the upper slipface and would then have to fail as

382　　granular avalanches dominated by grain-to-grain contacts. Table 3 summarizes the values of

383　　parameters in the Wallis-Lowe model as applied to the equilibrium dunes in this study.

384　　Comparison of the predicted maximum liquefied avalanche travel distances Γ with respect to the

385　　measured length of the slipface S_l shows that the putative liquefied avalanche would travel a

386　　fractional distance along the slipface of $\Gamma/S_l = 0.12\text{-}0.34$. This suggests that the dune slipface

387　　angles in this study are not controlled by liquefied avalanches, and are instead controlled by

388　　granular avalanches.

389   This result suggest that low lee angles can be maintained without liquefied avalanches.

390   The specific reason low lee angle dunes form in the light-weight sediments is not immediately

391   obvious. A likely explanation for the low slipface gradients in this study are that polystyrene

392   granular avalanches are able to travel on lower gradients compared to granular avalanches of

393   quartz density sand particles. The static angle of repose in water of the polystyrene particles is

394   24° (Table 1). The dynamic angle of repose is generally 3-10 ^{o} lower than the static angle (Al-

395   Hashemi and Al-Amoudi, 2018), which is consistent with the avalanche slipface angles of the

396   equilibrium polystyrene dunes herein (Table 2). In addition, angle of repose is affected by

397   particle shape, increasing with deviations from roundness and sphericity (Al-Hashemi and Al-

398   Amoudi, 2018). The measurements of roundness ($R = 0.46$) and sphericity ($S = 0.81$) of the

399   polystyrene particles show that the particles can be classified as subrounded (Hryciw et al.,

400   2016), which would result in steeper slipface angles compared to round and spherical particles of

401   the same density (Al-Hashemi and Al-Amoudi, 2018). Combined, the effects of relative

402   sediment density and roundness on the angle of repose produce low angle dunes in our

403   experiments without the liquefied avalanches described by Kostaschuk and Venditti (2019) over

404   dunes in deep rivers. We expect that experiments with rounder and more spherical polystyrene

405   particles would allow exploration of dunes with even lower slipface angles.

406   While the experiments suggest that light-weight sediments cannot be used to explore the

407   liquefied avalanches that dominate low lee angles in deep rivers, the particles do produce dunes

408   similar to those formed in deep rivers. This provides an opportunity to investigate flow

409   dynamics, roughness and form drag of actively migrating LADs at laboratory scale. The

410   experiments also point to other mechanisms that may control low lee angles for dunes close to

411   the threshold value estimated as 24°, such as dunes observed in the Río Paraná, Argentina (α ~

412   15°-24°; Parsons et al., 2005). The relative density of sediment evidently plays an important role

413   in the emergence of low lee angles, a phenomenon not readily evident for dunes formed in water

414   flows on Earth because there is so little variation in the relative density of sediment.

415   4.4. Implications for Modelling Dune Morphodynamics and Flow Resistance

416   These experimental findings are useful to get insight into sediment transport processes

417   associated with bedform growth that, in turn, could be used to verify and improve the approach

418   and performance of numerical models. Physics-based morphological models are increasingly

419   used to simulate bedform morphodynamics. The models range from simple to complex in terms

420   of both hydrodynamics and sediment transport (Tjerry and Fredsøe, 2005; Giri and Shimizu,

421   2006; Shimizu et al., 2009; Paarlberg et al, 2009; Niemann et al., 2010; Uchida and Fukuoka,

422   2013; Nabi et al., 2014; Khosronejad and Sotiropoulos, 2014; Nabi et al., 2015; van Duin et al.,

423   2017; Sun and Xiao, 2016; Lefebvre and Winter, 2016; Goll, 2017; Yamaguchi et al., 2020).

424   Most of these models include a parameterized spatial lag between sediment transport maximum

425   and topographic maximum, based either on bed slope effects, or a non-equilibrium sediment

426   transport relation using pick-up and deposition functions. One of the fundamental challenges is

427   to replicate the interaction between flow, sediment transport and morphology physically reliably.

428   The question regarding which approach replicates physically correct sediment transport and

429   morphological processes associated with bedform growth remains ambiguous. Given the fact that

430   the sediment transport formulations, used in most of the numerical models, are empirical or

431   semi-empirical, it is rather difficult to capture the physics of sediment transport associated with

432   bedform initiation and growth processes.

433   Our experimental findings shed some light on these underlying processes, revealing

434   spatial lag between sediment transport and bed morphology at different stages of dune growth.

435   The observed variation in this spatial lag is similar to findings from a numerical dune evolution

436   model with non-equilibrium sediment transport formulation in Yamaguchi et al. (2020). The

437   experimental results also highlight the sediment transport processes over the leeside of the dunes,

438   which include both the distribution of bed and suspended sediment transport. Another important

439   outcome of the experiment is the lower slipface angle, which could be useful for verifying

440   numerical models, since they usually predict higher slipface angles close to the angle of repose.

441   Moreover, the model concept of a bed slope effect used to simulate dune evolution and growth

442   even requires an avalanche function of sediment load over dune leeside to restrict the leeside

443   angle to the angle of repose. This should be explored in a future study with the numerical model

444   including similar lightweight materials as used in current experiments.

445   The experimental findings presented herein can be employed for detailed exploration and

446   verification of different sediment transport approaches in numerical models. This will help to

447   further verify model performance, as well as to improve fundamental aspects of sediment

448   transport approaches in numerical models. Another important aspect is the accurate prediction of

449   form drag exerted by bedforms. The numerical model must be verified for the case when the

450   slipface angle is lower than angle of repose. Consequently, it is necessary to explore the

451   evolution of form drag and its effect on water surface, particularly for the case with a lower

452   slipface angle as found in these experiments and in the field. Physical experiments and numerical

453   modelling can be combined to develop a generic method for assessing flow resistance.

5 Conclusions

Flume experiments were designed to study dune adaptation to an imposed flow, and in particular the mechanics of dune growth. The 3D bed topography was continuously monitored using a line laser scanner combined with a camera. High-resolution profiles of flow velocity and sediment concentration, providing direct estimations of both the bedload and the suspended load sediment flux, were obtained by deploying an Acoustic Concentration and Velocity Profiler. The main findings of our study are summarized as follows:

1. Dune slipface angles – determinative for flow separation and turbulence production – adjust to the imposed flow at time scales similar to the evolution of dune height and length.

2. The evolution of dune slipface angles reveals that as the onset angle for initiation of flow separation is exceeded, and trough scour is intensified, less sediment bypasses the flow reattachment point. This accelerates dune growth as more sediment arriving at the dune crest is maintained within the dune.

3. The sediment transport distribution illustrates distinct avalanching processes of bed material over dune leesides. Avalanching is characterized by an immediate decay of bedload transport over the dune leeside in presence of a flow separation zone. In absence of a flow separation zone, avalanching is more gradual, with sediment being deposited over dune leesides and much further into dune troughs.

747   **Table 1**. Overview of flow, sediment, and dune bed characteristics.

Parameter	Value
Discharge, Q [m^3 s^{-1}]	0.050
Water depth, H [m]	0.25
Flume slope, $S \times 10^{-3}$ [-]	1.0
Mean bulk velocity, U [m s^{-1}]	0.17
Froude number, Fr [-]	0.11
Bed shear stress, τ_b [Pa]	1.73
Bed shear velocity, u_* [m s^{-1}]	0.04
Suspension number, u_*/w_s [-]	1.43
Shields number, θ [-]	1.53
Transport stage, θ/θ_c [-]	47.8
Mean particle diameter, $D_{50} \times 10^{-2}$ [m]	0.21
Sediment density, ρ_s [kg m^{-3}]	1055
Settling velocity, w_f [m s^{-1}]	0.029
Critical Shields number, θ_c [-]	0.032
[a]Static angle of repose, β [degrees]	24.0
[b]Particle Roundness, R [-]	0.46
[c]Particle Sphericity, S [-]	0.81
Dune height in equilibrium, Δ_e [m]	0.083
Dune length in equilibrium, Λ_e [m]	1.43
Dune steepness, Δ_e/Λ_e [-]	0.058
Dune slipface angle in equilibrium, α_e [degrees]	19.8
Time needed for equilibrium, T_e [min]	125

748   [a]Static angle of repose of polystyrene particles is determined using the fixed funnel method
749   according to Al-Hashemi and Al-Amoudi (2018).
750   [b]Particle roundness quantifies the sharpness of particle corners calculated after the method
751   described by Zheng and Hryciw (2015), and Hryciw et al. (2016).
752   [c]Particle sphericity is the ratio of particle width to particle length.
753

Table 2. Model Fitting Results. Exponential phase results are from fits using Equation 1. Equilibrium dimensions are the asymptotes in Equation 1 plus the dimensions at the end of the linear growth phase. Following Baas (1994), Venditti et al. (2005), and Bradley & Venditti (2019), $T_{e;fit}$ is the time required for the growth curve to reach 99% of the asymptote.

| | Growth Phase | | | | | Equilibrium Dimension [m, °] | $T_{e;fit}$ [hr] |
| | Linear | | | Exponential | | | |
Dune property	Slope [-]	Intercept [m]	Phase end [hr]	a [m, °]	b [-]		
Height	0.0394	0.00890	0.650	0.0404	3.86	0.0811	1.91
Length	0.669	0.181	0.650	0.819	2.94	1.54	2.28
Slipface angle	-	-	-	19.1	1.51	19.1	3.05

760   **Table 3**. Parameters for the Wallis-Lowe model.

Parameter	Value
Initial deposit thickness, ζ [cm]	0.42-0.84
Slipface angle, α [°]	19.8
Density of liquefied avalanche, ρ_l [g cm^{-3}]	1.03
Density of water, ρ_f [g cm^{-3}]	1.00
Avalanche head velocity, u_h [cm s^{-1}]	2.40-3.41
Avalanche head thickness, Y [cm]	0.42-0.84
Resedimentation time, t [s]	0.56-1.12
Liquefied avalanche travel distance, Γ [cm]	1.34-3.88
Slipface length, S_l [cm]	11.25

761

764 **Figure 1.** Overview of the experimental set-up, (a) side view of the tilting flume with the
765 effective measurement section between x = 4 m to x = 8 m in streamwise direction, (b)
766 positioning of the line laser scanner on a semi-automatic carriage, (c) fully developed
767 equilibrium dunes, and (d) set-up of the Acoustic Concentration and Velocity Profiler (ACVP,
768 see Naqshband et al., 2014b for details).

769
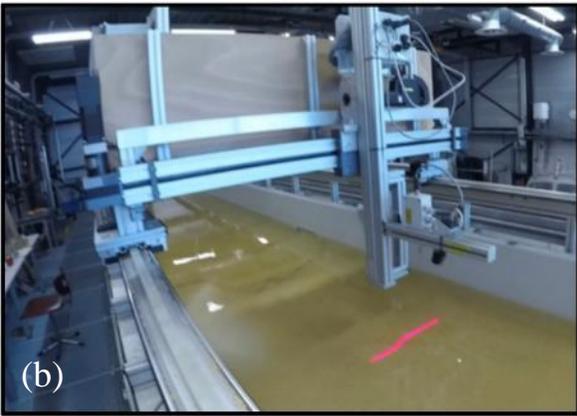

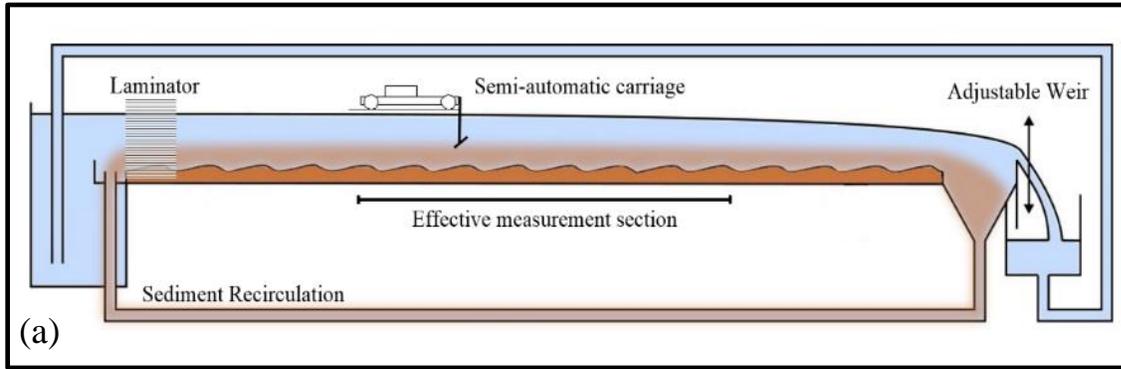

771 **Figure 2.** Different stages of bed morphology illustrating dune growth from an initial flatbed
772 towards a dynamic equilibrium with fully developed dunes, time evolves from top to bottom,
773 with T_e the time needed to reach a dynamic equilibrium from an initial flatbed.

(a) t/T$_e$ = 0.11

(b) t/T$_e$ = 0.21

(c) t/T$_e$ = 0.64

(d) t/T$_e$ = 0.87

distance across flume [m]

distance along flume [m]

bed elevation [mm]

774
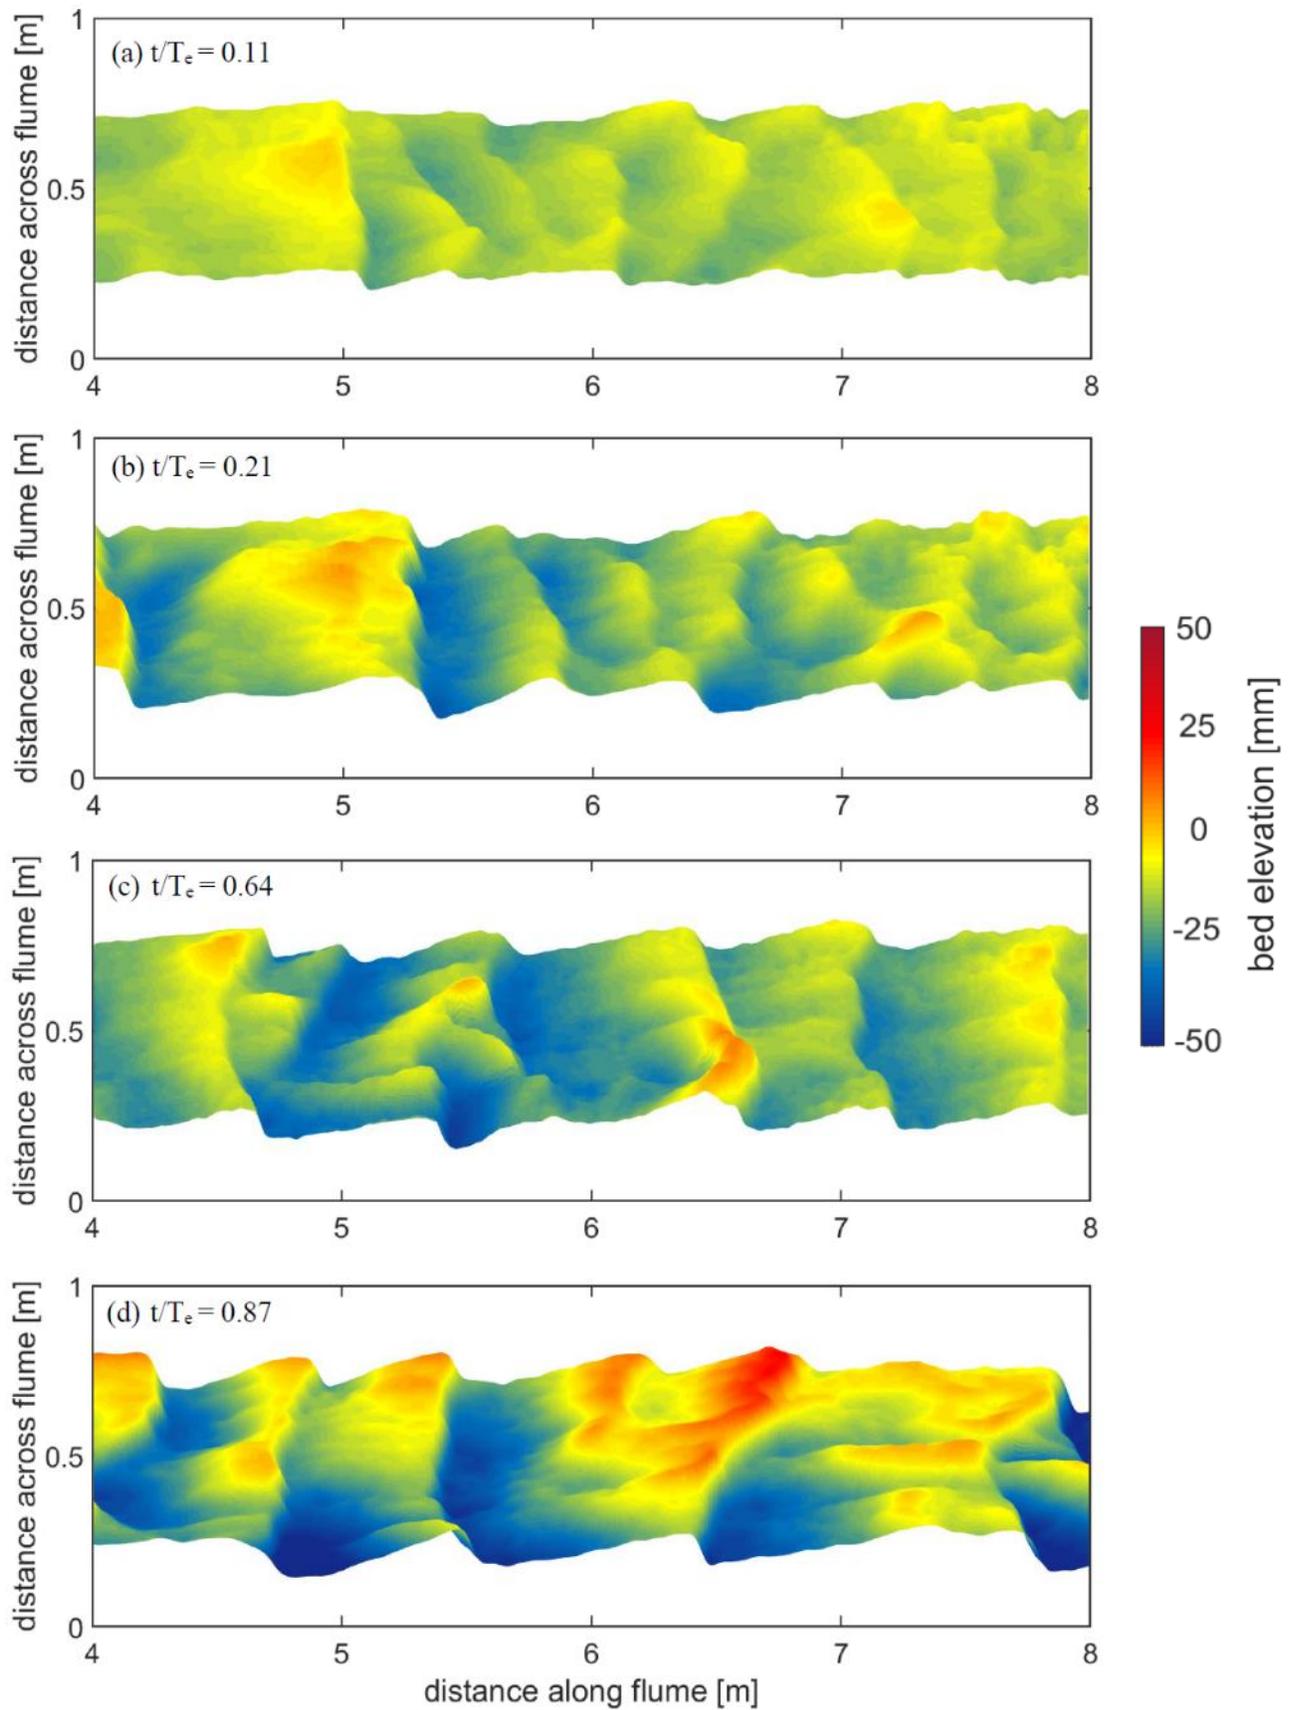

Figure 3. Morphological growth curves showing the evolution of dune dimensions over time, (a) relative dune height (Δ/Δ_e), (b) relative dune length (Λ/Λ_e), (c) dune steepness (Δ/Λ), and (d) dune slipface angle. T_e is the time needed to reach a dynamic equilibrium from an initial flatbed, shaded green area is mean values ± standard deviation. Red circles in (a) to (c) indicate the moment of transition between a linear and an exponential growth, which coincides with the time that the onset angle for initiation of flow separation is exceeded, indicated with red circle in (d).

795   **Figure 4.** Distribution of dune slipface angle at four different stages of dune development as
796   shown in Figure 1. The solid green lines represent kernel density fits to dune slipface data with
797   circles indicating spatially averaged values.
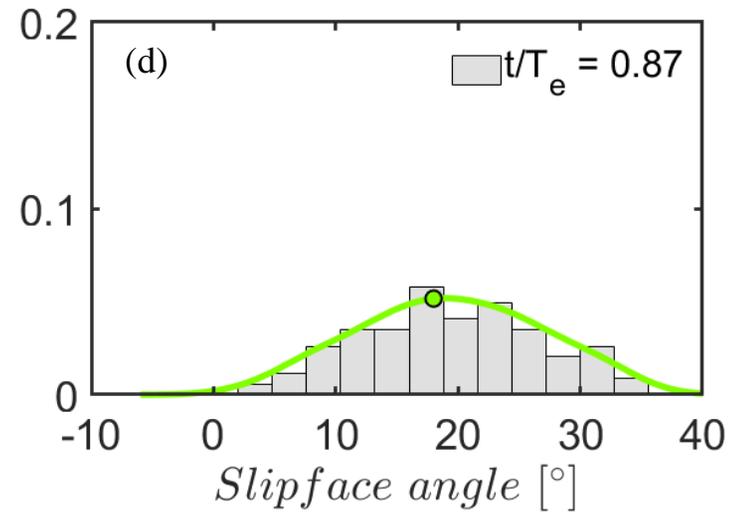

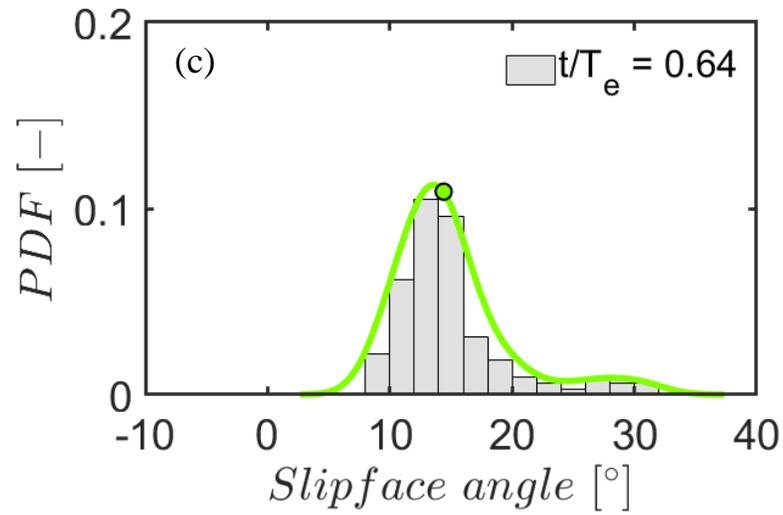

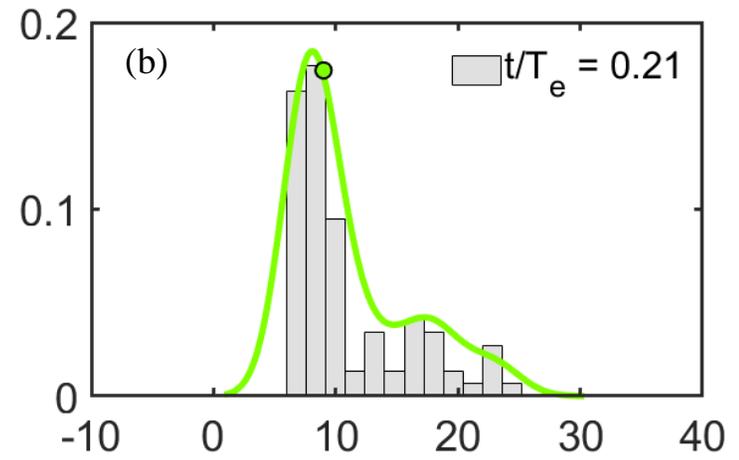

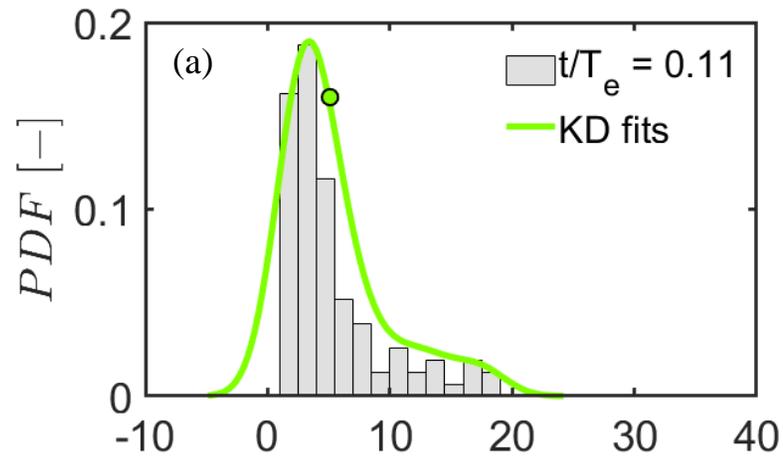

799   **Figure 5.** Flow field over mobile dunes, with (a) mean streamwise flow velocity and (b) mean
800   vertical flow velocity. Arrows represent the mean velocity vector field $\boldsymbol{V}(\overline{u}, \overline{w})$. Flow direction is
801   from left to right with measured dune profile in solid black line. Open black circle indicates the
802   location of flow reattachment point. An equivalent distance is derived from transforming ACVP
803   measurement time series into streamwise distance along the flume, using mean bed displacement
804   (see section 2).

805
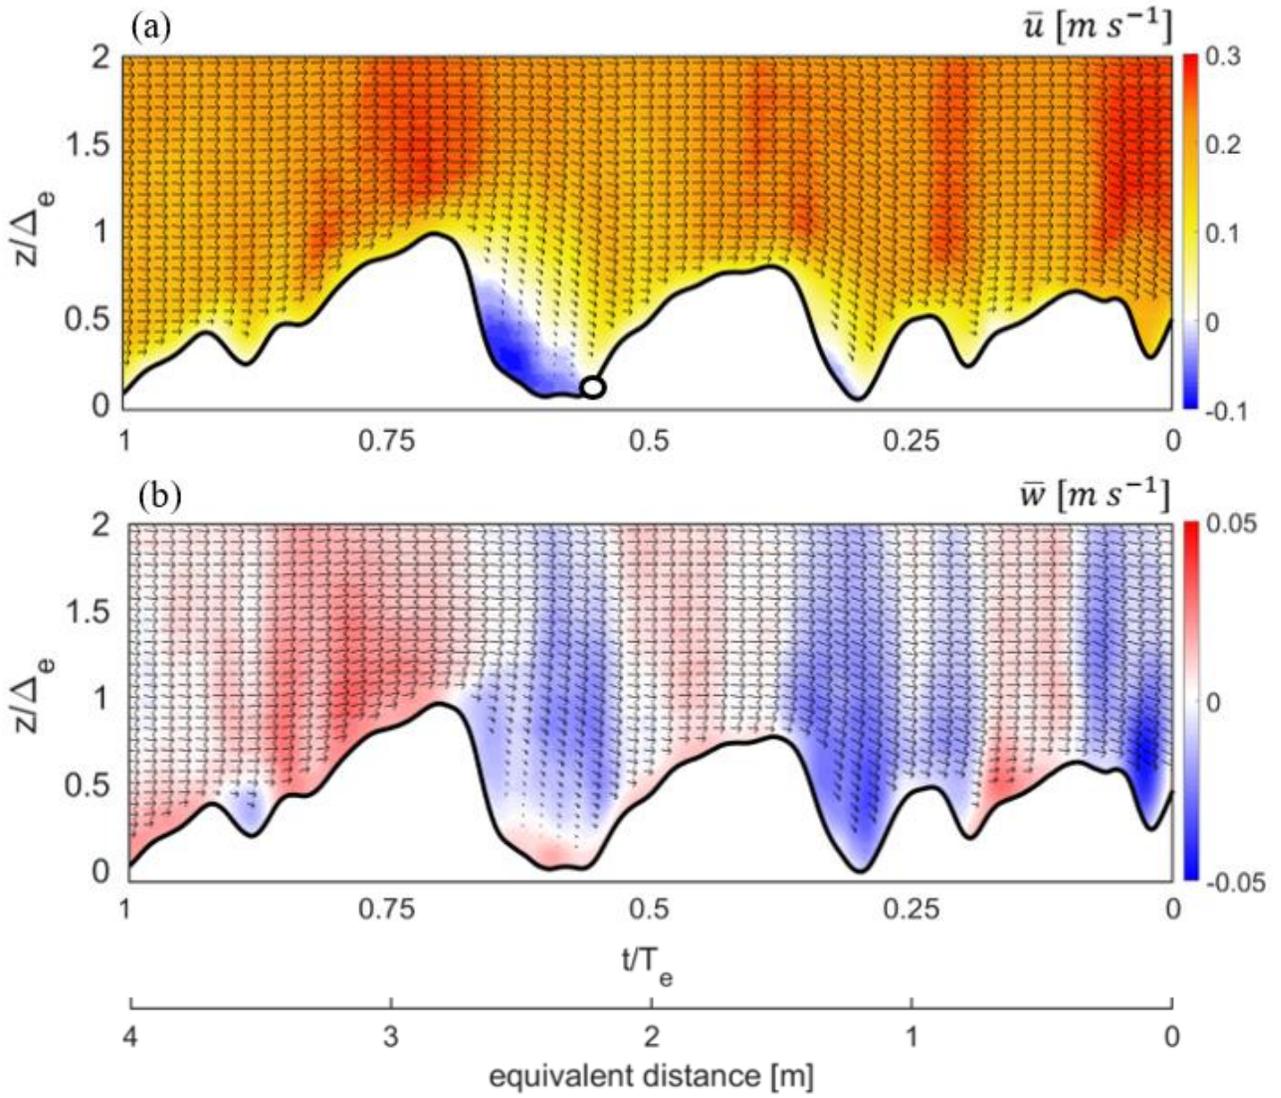

Figure 6. Sediment concentration and fluxes over mobile dunes, with (a) mean sediment concentration, (b) mean streamwise sediment flux, and (c) mean vertical sediment flux. Solid black line is the measured dune profile.
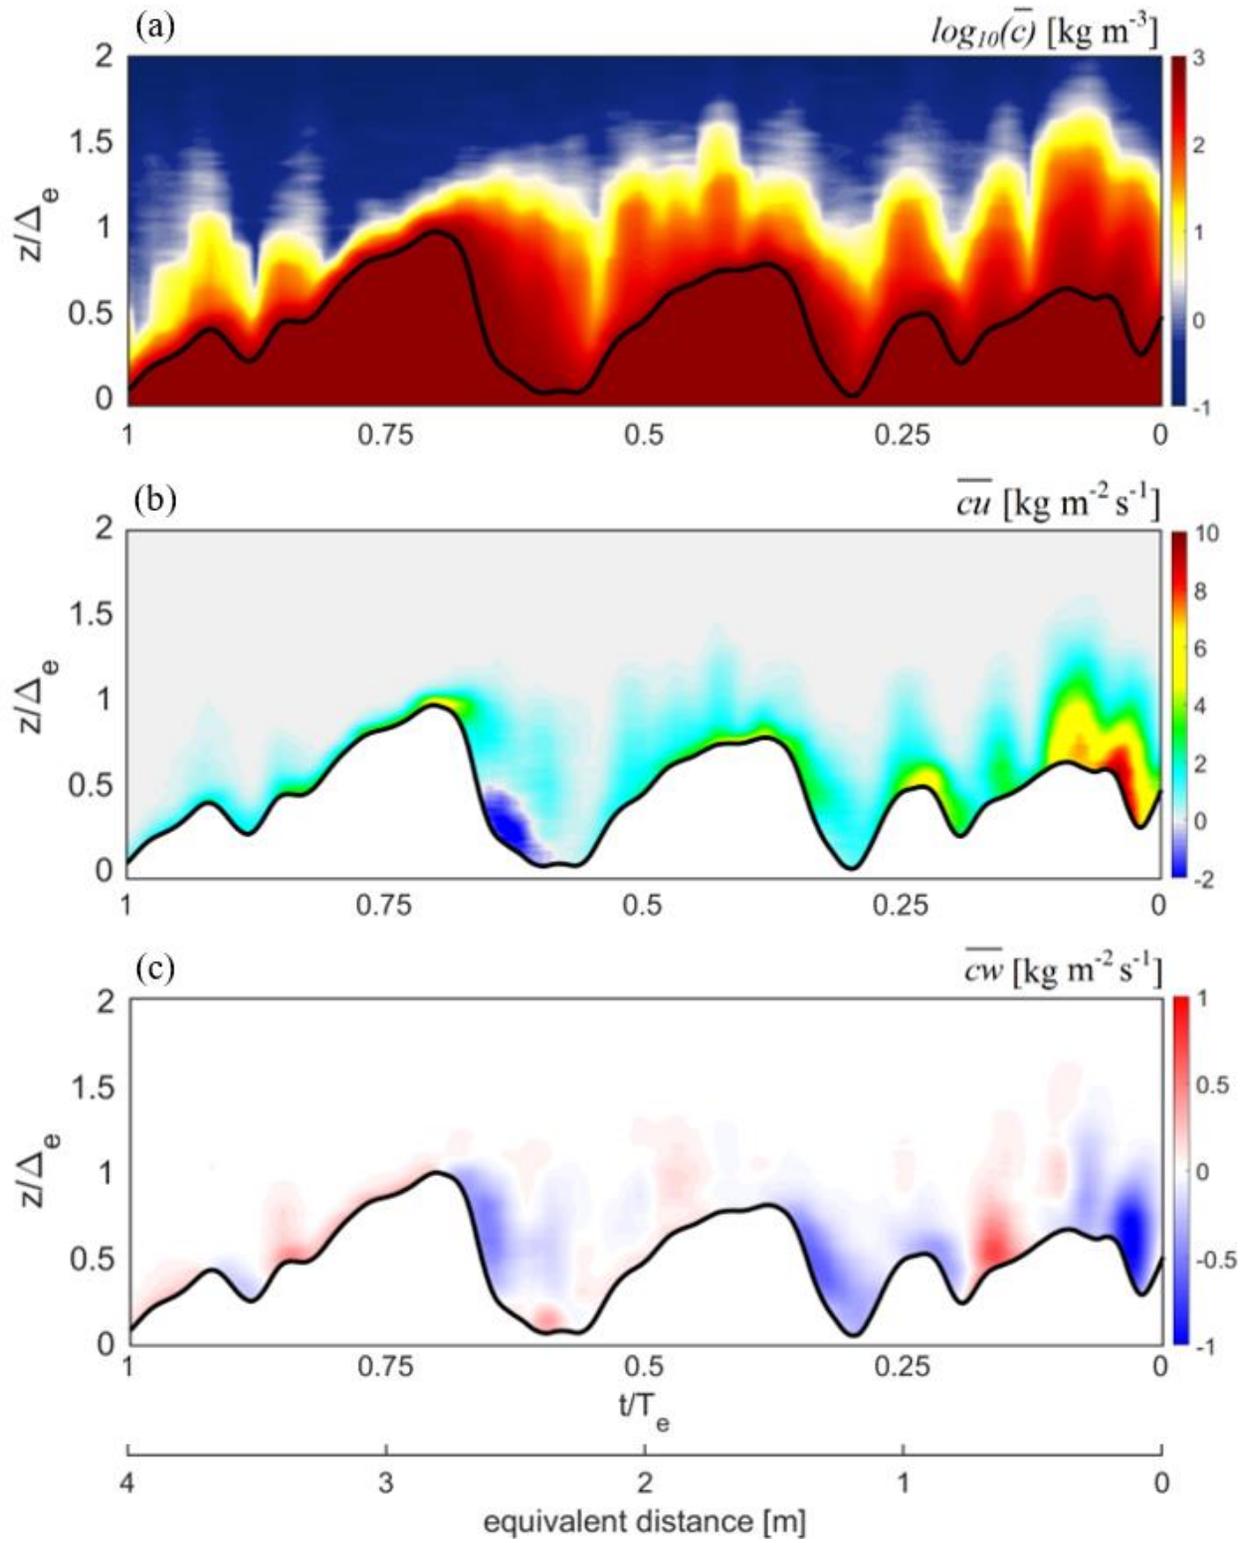

813   **Figure 7.** Sediment transport distribution over mobile dunes, with (a) showing total load, (b)
814   bedload, and (c) suspended load transport. Solid black line is the measured dune profile, with
815   black open circle the location of flow reattachment point. Orange circles in (a) indicate the
816   location of dune-maximum sediment transport, relative to dune topographic maximum (open
817   gray   circle).
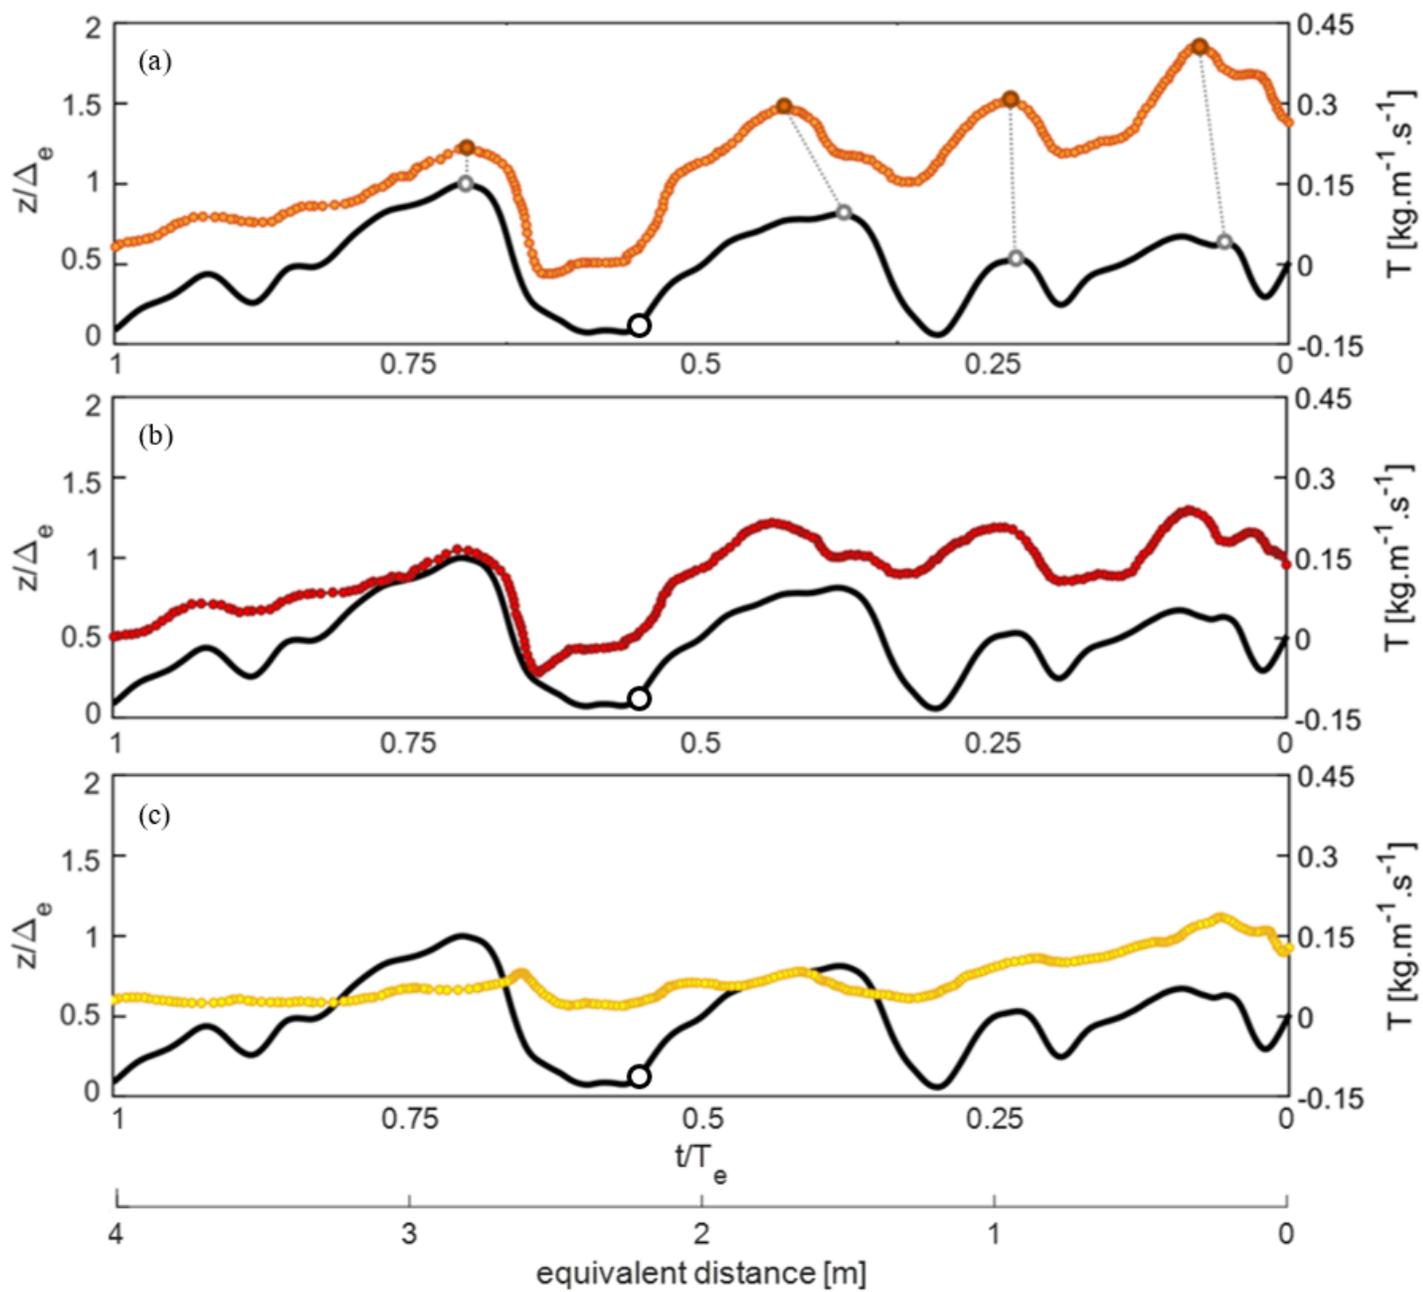

819   **Figure 8.** Growth curve fits through time with (a) height, (b) length, and (c) slipface angle. (a)
820   and (b) display punctuated growth, where a period of linear growth is followed by exponential
821   growth, while (c) shows only exponential growth (see Table 2 for model fitting results).
