Key Points:

- Regional and global trends in top-of-atmosphere net radiation from atmospheric reanalyses differ markedly from satellite observations

- Indirect and direct methods for determining divergence of atmospheric energy transport and surface flux yield similar trend patterns

- Observing system changes and model bias in atmospheric and oceanic reanalyses remain a challenge for accurate trend determination

- Our results highlight a central role for well-calibrated satellite observations in establishing trend patterns in nature

- Robust trends are observed over the Gulf Stream associated with enhanced surface-to-atmosphere heat flux

Abstract

Satellite, reanalysis, and ocean in situ data are analyzed to evaluate regional, hemispheric and global mean trends in Earth's energy fluxes during the first twenty years of the 21st century. Regional trends in net top-of-atmosphere (TOA) radiation from the Clouds and the Earth's Radiant Energy System (CERES), ECMWF Reanalysis 5 (ERA5), and a model similar to ERA5 with prescribed sea surface temperature (SST) and sea ice differ markedly, particularly over the Eastern Pacific Ocean, where CERES observes large positive trends. Hemispheric and global mean net TOA flux trends for the two reanalyses are smaller than CERES, and their climatological means are half those of CERES in the southern hemisphere (SH) and more than nine times larger in the northern hemisphere (NH). The regional trend pattern of the divergence of total atmospheric energy transport (TEDIV) over ocean determined using ERA5 analyzed fields is similar to that inferred from the difference between TOA and surface fluxes from ERA5 short-term forecasts. There is also agreement in the trend pattern over ocean for surface fluxes inferred as a residual between CERES net TOA flux and ERA5 analysis TEDIV and surface fluxes obtained directly from ERA5 forecasts. Robust trends are observed over the Gulf Stream associated with enhanced surface-to-atmosphere transfer of heat. Within the ocean, larger trends in ocean heating rate are found in the NH than the SH after 2005, but the magnitude of the trend varies greatly among datasets.

1. Introduction

Earth's energy flows encompass the exchange of energy between Earth and space and between Earth's atmosphere, ocean, lithosphere, and cryosphere. These exchanges occur over a range of time and space scales and influence weather and climate at any given location and time. A thorough understanding of Earth's energy flows is thus necessary in order to project how regional and global climate will change in response to radiative forcing. Observations of Earth's energy flows are essential for evaluating and improving the climate models used to make these projections. Ideally, the observations must provide accurate descriptions of the mean state of Earth's energy flows as well as their variations on seasonal, interannual, and decadal time scales.

Efforts aimed at quantifying Earth's mean energy flows date back to the early 20th century (Hunt et al., 1986). So-called "radiation budget diagrams" of global mean values of shortwave and longwave radiation within the climate system first appeared in 1908 (Abbot and Fowle, 1908 a, b). These diagrams were later extended to include non-radiative contributions (Dines, 1917; London, 1957). Energy budget diagrams were further refined following the launch of the first orbiting satellites, which included instruments designed to observe Earth's radiation budget (ERB; House et al., 1986). A key advance was made by Keihl and Trenberth (1997), who used adjusted global mean top-of-atmosphere (TOA) radiative fluxes from the Earth Radiation Budget Experiment (ERBE), surface radiative fluxes derived from radiative transfer calculations, surface latent heat flux inferred from estimates of global mean precipitation, and sensible heat flux determined as a residual ensuring a global energy balance at the surface. Subsequent studies by Trenberth et al. (2009), Stephens et al. (2012), Wild et al. (2013) and L'Ecuyer et al. (2015) further refined the global mean energy budget diagram using increasingly more sophisticated datasets and analysis techniques.

75   Early efforts aimed at quantifying energy transports within the climate system focused

76   primarily on meridional transports (e.g., Vonder Haar and Oort 1973; Oort and Vonder Haar 1976;

77   Trenberth 1979) using satellite observations to determine the required total energy transport and

78   radiosonde data to determine the atmospheric transports. The ocean transport was then computed

79   as a residual. Alternately, the ocean heat transport was also determined directly using hydrographic

80   cross sections of temperature and salinity (Bryan, 1982). However, both approaches suffered from

81   large sampling errors due to lack of data coverage over the oceans. The use of reanalysis combined

82   with satellite observations of ERB for determining atmospheric and oceanic transports

83   significantly reduced sampling error (Masuda, 1988; Trenberth and Caron, 2001), leading to more

84   reliable results compared to the earlier studies. Furthermore, Trenberth and Fasullo (2017) show

85   that surface fluxes derived as a residual between satellite TOA net downward radiation and

86   estimates of the divergence of the vertically integrated atmospheric energy from reanalysis

87   overcome many of the known issues in determining surface flux directly—such as near-surface

88   meteorological variables and bulk flux parameterizations (Yu et al., 2019).

89   The combination of ERB satellite and atmospheric reanalysis has been used not only to

90   study the global mean energy budget and mean meridional transports but also their annual cycles

91   and land-ocean exchanges (Fasullo and Trenberth, 2008a,b), cross-equatorial heat transports

92   (Trenberth and Fasullo, 2008; Donahoe et al., 2013; Frierson et al., 2013; Marshall et al., 2013;

93   Loeb et al., 2015; Mayer et al., 2017; Liu et al., 2020), as well as El Niño–Southern Oscillation

94   (ENSO) and other interannual variability (Loeb et al., 2014; Mayer et al. 2014; Trenberth and

95   Fasullo, 2017). Recently, refinements have been made to the formulation of the atmospheric

96   energy budget to include contributions from vertical enthalpy fluxes at the surface associated with

97   precipitation and evaporation (Mayer et al., 2017; Trenberth and Fasullo, 2018; Kato et al., 2021).

4

98   It has recently been demonstrated that TOA ERB data from the Clouds and the Earth's

99   Energy System (CERES) provide robust trends since 2000 (Loeb et al., 2021). At the same time,

100   there has been tremendous progress made in atmospheric and ocean reanalysis systems, with new

101   versions seeing improvements over their predecessors as a result of updates to the underlying

102   model, assimilation system and input data stream (Dee et al. 2014; Buizza et al. 2018; Hersbach

103   et al. 2020; Gelaro et al., 2017; Storto et al., 2019; Zuo et al., 2019, 2021).

104   A question that has yet to be addressed in detail is to what extent can we trust multi-decadal

105   time-scale trends in different components of Earth's energy budget and energy flows within the

106   climate system. Here "trend" refers to the relatively short 20-year period since 2000, which is

107   likely influenced by both anthropogenic forcing and internal variability (Raghuraman et al., 2021).

108   We do not expect that these trends are necessarily representative of longer-term trends, though

109   aspects have been tied to climate change (e.g. Hartmann and Ceppi 2014). Rather our goal is to

110   investigate the strengths and weaknesses of using observation based data to determine trends in

111   TOA radiation, atmospheric energy transport, surface flux, and ocean heating rate. The latter is

112   determined from the tendency in OHCA. While evaluations of atmospheric reanalyses for trends

113   in atmospheric moisture transport (Trenberth et al., 2011) and latent heat flux (Robertson et al.,

114   2020) have been conducted, similar analyses for other components of Earth's energy budget are

115   lacking.

116   We limit our investigation to satellite observations from CERES, atmospheric and oceanic

117   reanalysis from the European Centre for Medium-Range Weather Forecasts (ECMWF), and ocean

118   heating rate calculations benefiting from data collected by the revolutionary Argo array of profiling

119   floats (mapped alone, mapped in combination with sea-surface height data from satellite

120   altimeters, and assimilated into reanalyses). The limited number of datasets used enables a more

121   focused assessment of the impact data assimilation in reanalysis on trends. In addition, to our

122   knowledge, ECMWF data are the only source that have been used to calculate the divergence of

123   lateral atmospheric energy transports using the most recent methodological advances (Mayer et

124   al., 2021). The datasets used in the analysis are described in Section 2. This is followed by a

125   description of the methodology applied to the data in Section 3, and results are presented in Section

126   4. A summary of our main findings are provided in Section 5.

127

128   **2. Data**

129   We use TOA and surface radiation fields from CERES and ECMWF reanalyses, total

130   atmospheric energy transport estimates from those same ECMWF reanalyses, as well as ocean

131   heating rate estimates derived from two different ECMWF ocean reanalyses, an observational

132   product combining Argo temperature profiles with sea-surface height maps from satellite

133   altimeters, and an Argo-only observational product.

134   **2.1 CERES TOA and Surface Radiation Data**

135   Satellite radiation data are from the CERES Energy Balanced and Filled (EBAF) Ed4.1

136   product (Loeb et al., 2018a), which provides monthly mean TOA and surface shortwave (SW),

137   longwave (LW), net (NET) radiative fluxes and solar irradiance measurements on a 1°×1° grid

138   along with imager-derived cloud properties. TOA absorbed solar radiation (ASR) is determined

139   from the difference between spatially and temporally averaged monthly solar irradiances and

140   reflected SW fluxes. The solar irradiances are determined from time-varying instantaneous total

141   solar irradiance measurements from various sources (Loeb et al., 2018). Satellite incoming and

142   outgoing radiative fluxes are presently not at the level of accuracy required to resolve TOA fluxes

143   to a few tenths of a Wm^{-2} in an absolute sense (Loeb et al., 2018). However, CERES TOA fluxes

144　are highly precise as the instruments are very stable (Loeb et al., 2016; Loeb et al., 2018b; Shankar

145　et al., 2020; Loeb et al., 2021). The EBAF product uses an objective constrainment algorithm

146　(Loeb et al., 2009) to adjust SW and LW TOA fluxes within their ranges of uncertainty to remove

147　the inconsistency between average global net TOA flux and heat storage in the earth–atmosphere

148　system, determined primarily from ocean heat content anomaly (OHCA) data (Johnson et al.,

149　2016). Use of this approach to anchor the satellite EEI to the in situ EEI does not affect the

150　variability and trends in the data.

151　　　We also use TOA fluxes from the Terra and Aqua CERES SSF1deg Ed 4.1 products

152　(Doelling et al., 2013; Loeb et al., 2018a) in order to compare CERES fluxes from different satellite

153　platforms. Unlike CERES EBAF, which combines CERES instruments on different satellites,

154　SSF1deg is determined separately for each satellite CERES instruments fly on. The CERES

155　SSF1deg product is derived directly from the CERES Single Scanner Footprint TOA/Surface

156　Fluxes and Clouds (SSF) Level 2 product, which consists of instantaneous footprint-level fluxes.

157　　　Two sources of surface radiation are considered. The first is from the CERES EBAF Ed4.1

158　product (Kato et al., 2018) and the second is Aqua-only SYN1deg-Month. EBAF Ed4.1 surface

159　fluxes are derived by making adjustments to the inputs used to compute all-sky and clear-sky

160　surface fluxes in SYN1deg Ed4.1 (Rutan et al., 2015). The adjustments ensure that computed and

161　EBAF-observed TOA radiative fluxes agree to within observational uncertainty. The modified

162　inputs are then used to derive surface radiative fluxes that are self-consistent with the observed

163　EBAF TOA fluxes. The SYN1deg surface radiative fluxes are determined from radiative transfer

164　model calculations initialized using cloud inputs from the Moderate Resolution Imaging

165　Spectroradiometer (MODIS) instruments aboard the Terra and Aqua satellite platforms and hourly

166　geostationary (GEO) imager data between 60°S-60°N, atmospheric state inputs from the Goddard

167   Earth Observing System (GEOS), version 5.4.1, reanalysis (Rienecker et al. 2008), surface albedo

168   inputs from Rutan et al. (2009), and aerosol inputs based upon an updated version of the

169   assimilation system described in Collins et al. (2001).

170   Because trends in surface radiative fluxes derived using cloud information from GEO

171   imagers are impacted by changes in the design and quality of the GEO instruments over the CERES

172   period (Doelling et al., 2013; Kato et al., 2018), we also determine surface fluxes using a modified

173   version of SYN1deg, which we refer to as Aqua-only SYN1deg-Month. This version uses the same

174   atmospheric state and surface property inputs as Terra+Aqua+GEO SYN1deg-Month, but replaces

175   the GEO cloud properties with those derived from MODIS-Aqua only (Minnis et al., 2020).

176   Instantaneous MODIS cloud retrievals are averaged into 1°×1° grid boxes. MODIS-Aqua provides

177   cloud properties twice a day for most of non-polar grid boxes. Hourly daytime cloud properties for

178   a grid box are derived by interpolating daytime cloud properties from MODIS across days within

179   a month for the grid box (Doelling et al, 2013). Hourly nighttime properties for a grid box are

180   derived in a similar manner using nighttime MODIS cloud properties. In addition, daytime or

181   nighttime monthly mean cloud properties are used for all hours before the first MODIS

182   observations in the month and after the last MODIS observations in the month. That is, there is no

183   interpolation of cloud properties across different months. In addition, the MATCH aerosol

184   transport model used in Aqua-only SYN1deg-Month only assimilates aerosol optical thickness

185   derived from MODIS Aqua as opposed to both Terra and Aqua for Terra+Aqua+Geo SYN1deg-

186   Month. Aqua-only surface net shortwave and longwave flux trend plots are determined using

187   anomalies for August 2002-February 2020 since that is the period for which Aqua-only SYN is

188   available.

2.2 ERA5 and Integrated Forecasting System (IFS) AMIP

189

190   ERA5 is the most recent atmospheric reanalysis effort by ECMWF (Hersbach et al., 2020).

191 It provides global data on an N320 Gaussian grid (equivalent to 0.288° spatial resolution) at 1-

192 hourly temporal resolution in 137 atmospheric levels up to a pressure of 0.01 hPa. ERA5 is

193 currently available from 1979 onward and consists of analyses and shortrange forecasts. The

194 analyses are a physically consistent blend of observations and a short-range forecast based upon

195 the previous analysis. Shortrange forecasts are initialized from the analyzed fields daily at 0600

196 and 1800 UTC. ERA5 uses forcing files from CMIP5 through 2005 and Representative

197 Concentration Pathways 2.6 (RCP2.6) for 2006-2020 (Hersbach et al., 2015, 2020).

198   Here we use profiles of hourly ERA5 analyses of atmospheric wind, temperature, and

199 humidity to calculate vertically integrated divergence of total atmospheric energy transport

200 (TEDIV; Section 3.1). We also consider ERA5 short-term forecasts of TOA and surface radiative

201 fluxes as well as surface turbulent heat fluxes for a check on model fidelity.

202   The IFS AMIP is a continuous atmospheric model integration with a similar setup as

203 ERA5, but uses a slightly newer model cycle. It is initialized in March 2000 and integrated until

204 the end of February 2020 without data assimilation, but with prescribed SSTs and sea ice.

2.3 Ocean Data

205

206   The Ocean and sea-ice ReAnalyses System 5 (ORAS5) (Zuo et al., 2019) is a reconstruction

207 of ocean and sea-ice states derived from an ocean-sea-ice coupled model driven by atmospheric

208 surface forcing and constrained by ocean observations using data assimilation (Balmaseda et al.,

209 2015). It consists of a behind-real-time component of the OCEAN5 ocean reanalysis-analysis

210 system at ECMWF. The ocean model and data assimilation method are kept frozen during the

211 production of the reanalysis. The Ocean ReAnalysis Pilot system-6 (ORAP6) is a new ocean and

212   sea-ice reanalysis system that has been developed based on the ECMWF operational OCEAN5

213   system (Zuo et al., 2021). Despite sharing the same model configurations as OCEAN5, ORAP6

214   uses updated atmospheric forcing (based on ERA5) and is produced with the most up-to-date

215   reprocessed observation datasets. The ORAP6 data assimilation system has been updated to

216   include a new flow-dependent SST nudging scheme, and to assimilate L3 sea-ice concentration

217   data, among others. ORAP6 uses 3DVar to assimilate in-situ temperature and salinity profiles from

218   Argo, Moorings, XBTs, shipboard CTDs, gliders, and marine mammals, satellite sea-level

219   anomaly and sea-ice concentration data, as well as SST and sea-surface salinity (SSS) nudging in

220   the surface (Zuo et al., 2021). Two sets of ocean data from ORAP6 system have been used in this

221   study. ORAP6.1 is the first version of ORAP6 reanalysis that includes assimilation of all

222   observations. We also consider a control version of ORAP6.1 called "ORAP6-ctrl", which uses

223   the same model setup and atmospheric forcing (from ERA5) as ORAP6.1, but only uses SST and

224   SSS nudging at the surface. The difference between ORAP6.1 and ORAP6-ctrl thus indicates the

225   impact of data assimilation on ocean heating rates.

226   In addition to the above ocean reanalyses, we determine ocean heating rates from two Argo-

227   based datasets. The first is an Argo-only time series obtained from the combination of a 10/2021

228   update of the Roemmich and Gilson (2009) climatology and the Asia-Pacific Data-Research

229   Center's Argo gridded 3°x3° monthly product on standard depth levels, documented online (at

230   http://apdrc.soest.hawaii.edu/projects/Argo/index.php). The second Argo-based dataset is an

231   updated version of the 0–2,000 m ocean heat uptake estimate used in Loeb et al. (2021), which is

232   based upon Argo in-situ and satellite altimetry data. It uses local correlations between sea-surface

233   height and ocean heat content anomalies to employ satellite altimetry data as a first guess at ocean

234   heat content where (or when) in situ temperature data are sparse (Willis et al., 2003).

235 **3.0 Methodology**

236 **3.1 Inferred Surface Total and Turbulent Heat Fluxes**

237   The surface energy flux (F_S) defined here as positive downwards is inferred using the residual

238 method from the atmospheric energy budget (Trenberth and Fasullo, 2017; Mayer et al., 2017; Liu

239 et al., 2020) as follows:

240 $$F_S = F_{TOA} - \nabla \cdot F_A - AET \qquad (1)$$

241 where F_{TOA} is the net downward radiation at the TOA, $\nabla \cdot F_A$ is the divergence of lateral

242 atmospheric energy transports (TEDIV), and AET is the vertically integrated atmospheric energy

243 tendency. We use CERES EBAF Ed4.1 to determine F_{TOA}. The $\nabla \cdot F_A$ term is computed from

244 hourly ERA5 analyses of atmospheric wind, temperature, and humidity profiles using an improved

245 budget formulation that treats lateral and vertical moisture enthalpy fluxes in a consistent manner

246 (Mayer et al., 2017) and ensures mass consistency following J. Mayer et al. (2021). Maps of $\nabla \cdot F_A$

247 are smoothed using a tapered filter truncating at T42. The AET term is calculated from differences

248 of analyses of the total atmospheric energy at the first of each month, but AET is small on the time

249 scales considered.

250   In addition to the estimates described above, availability of ERA5 short-term forecasts and

251 IFS AMIP data provides two additional estimates of F_{TOA} and F_S and two alternative estimates of

252 $\nabla \cdot F_A$. For ERA5, we use short term forecasts and subtract F_{TOA} and F_S (Eq 1). Neglecting the

253 effect of assimilation increments in this estimate will lead to differences with the divergence

254 estimate based on analysed state quantities (J. Mayer et al 2021). The short-term ERA5 forecasts

255 are initialized from analyses that are constrained by observations and in that sense are still

256 influenced by observations. The divergence estimate from short-term forecasts can thus be viewed

257 as falling somewhere between an analysis-based estimate and an estimate from a free-running

258 model. The difference between divergence trends estimated from analyses and short-term forecasts

259 provides insight into the degree to which the model can represent observed changes in the

260 atmosphere. It may also reveal areas where the model damps out potential spurious jumps from

261 changes in the observing system. The third divergence estimate is similar to the one based on short-

262 term forecasts but uses IFS AMIP data. Trends in that estimate reflect changes the model captures

263 due to changes in the boundary conditions like SSTs and sea ice.

264   We determine "inferred" surface turbulent heat fluxes from:

$$Q_S = H_L + H_S = F_S - R_S \tag{2}$$

266 where Q_S is the sum of surface latent (H_L) and sensible (H_S) heat flux and R_S is net downward

267 radiation at the surface. We determine R_S from CERES.

3.2 Trends

269   Trends are determined from deseasonalized monthly anomalies using least squares linear

270 regression. To determine trend uncertainties, we first calculate residuals of the linear regression fit

271 to a monthly anomaly time series. Next, we calculate the autocorrelation function (ACF) of the

272 residuals and assess whether or not the ACF at any lag is significant by comparing it with

273 confidence intervals given by:

$$CI_k = \pm t_\alpha \sigma_k \tag{3}$$

275 where t_α is the student-t statistic at significance level α and σ_k is the standard deviation at lag k

276 derived using the formulation in Mélard and Roy (1987):

$$\sigma_k^2 = \frac{1}{N}\left(1 + 2\sum_{i=1}^{k-1} \rho_i^2\right) \tag{4}$$

278 where N is the number of samples and ρ_i is the ACF at lag i. If ρ_i at any lag lies outside the

279 confidence intervals in Eq. (3), we account for autocorrelation in determining the trend uncertainty

280 by calculating the effective sample size following Gelman et al. (2013):

12

281
$$N_e = \frac{N}{1 + 2\sum_{i=1}^{m} \rho_i} \tag{5}$$

282   We determine m as the first lag satisfying both $\rho_{m+1} < 0$ and $\rho_{m+1} + \rho_{m+2} < 0$. This criterion

283   minimizes uncertainty associated with sampling noise in the ACF. If none of the ρ_i fall outside the

284   confidence intervals, we assume the effective sample size (N_e) is equal to N. Once N_e is known,

285   Eqs. 3-5 in Santer et al. (2000) are used to calculate the trend uncertainty. While trend uncertainties

286   are evaluated using 2.5–97.5% confidence intervals, we set α=0.8 in Eq. (3) (corresponding to 10-

287   90% confidence intervals) in order to use a less stringent test for autocorrelation in the data. In

288   practice, we generally find statistically significant autocorrelation for monthly data but that is not

289   always the case when using annual mean data with a short 20-year record.

290   **4.0 Results**

291   **4.1 Top-of-Atmosphere**

292   Regional trends in TOA net radiation for 03/2000-02/2020 show marked differences

293   between CERES, ERA5 and IFS AMIP (Figs. 1a-c). As noted in prior studies (Myers et al., 2018;

294   Loeb et al., 2018b, 2020), CERES shows pronounced positive trends in net TOA flux over the

295   Eastern Pacific Ocean off of North America. This increase is driven mainly by an ASR increase

296   associated with a reduction in low cloud cover, which in turn is due to increasing SSTs (Myers et

297   al., 2018; Loeb et al., 2018b; Mayer et al., 2018). In contrast, ERA5 shows negative net TOA flux

298   trends throughout most of the Eastern Pacific Ocean region (Fig. 1b), while IFS AMIP shows

299   weaker positive trends and stronger positive trends along the equator (Fig. 1c). That neither ERA5

300   nor IFS AMIP capture the large positive trend off the west coast of North America observed by

301   CERES may suggest that the low cloud response to SST change is too weak in ERA5 and IFS

302   AMIP. In a similar comparison between CERES and seven CMIP6 models run in AMIP mode

303   (Loeb et al., 2020), most of the models showed increases in net TOA flux in this region but the

304 magnitude of the change varied amongst the models. Over the Arctic, CERES shows weak trends

305 in net TOA flux—the result of a cancellation between larger trends in ASR and outgoing longwave

306 radiation (not shown). Net TOA flux trends over the Arctic from IFS AMIP are closer to CERES

307 than ERA5, which shows strong negative trends. All three products show positive net TOA flux

308 trends along the climatological Arctic sea ice edge, where the net radiative effect of the retreating

309 sea ice is visible as noted in Hartmann and Ceppi (2014). ERA5 and IFS AMIP show better

310 agreement with CERES over the Atlantic off the coast of North America, to the southwest of Spain

311 and in the west-east trend dipole in the Indian Ocean around 20°-30°S. There is also very good

312 agreement over the sea ice regions off the coast of Antarctica.

313   Average southern hemisphere (SH) and northern hemisphere (NH) TOA fluxes from

314 CERES for 03/2000-02/2020 show hemispheric symmetry in ASR, stronger LW cooling in the

315 NH, and a larger net heat uptake in the SH (Table 1). The hemispheric asymmetry in net TOA flux

316 requires a 0.17 PW SH-to-NH cross-equatorial heat transport by the ocean-atmosphere system for

317 energy budget closure (Donohoe et al., 2013; Frierson et al., 20013; Marshall et al., 2013; Loeb et

318 al., 2016; Liu et al., 2020). With the exception of NH ASR, the ERA5 ASR and −OLR values in

319 Table 1 fall within the 95% uncertainty of CERES (Loeb et al., 2018a). However, ERA5 mean net

320 fluxes are about half as large as CERES in the SH and more than nine times larger in the NH, while

321 the global mean difference is only 0.05 Wm^{-2}. The ERA5 hemispheric asymmetry in mean net

322 TOA flux implies a −0.006 PW SH-to-NH cross-equatorial heat transport by the ocean-atmosphere

323 system, which is in marked contrast to CERES. For IFS AMIP, the discrepancy with CERES is

324 even greater as the hemispheric contrast in net TOA flux implies a −0.22 PW SH-to-NH cross-

325 equatorial heat transport, and the global mean net flux is negative, both of which are unrealistic.

326 The latter is related to model inconsistencies in the version of the IFS used (see Roberts et al.

327 2018). A possible reason for the inconsistent hemispheric values could be due to an unrealistic

328 representation of how clouds are distributed between the hemispheres in ERA5 and IFS AMIP.

329 Stephens et al. (2015) showed that increased reflection by clouds in the SH offsets greater

330 reflection by the larger land mass in the NH, resulting in hemispheric symmetry in albedo.

331 Anomaly standard deviations and trends in ASR, −OLR and NET are fairly symmetric

332 between the hemispheres for CERES (Table 1). The hemispheric trends in CERES between SH

333 and NH differ by only 0.07 Wm^{-2} per decade for ASR, 0.01 Wm^{-2} per decade for −OLR, and 0.08

334 Wm^{-2} per decade for NET, implying an insignificant 0.02±0.1 PW change to the combined ocean-

335 atmosphere cross-equatorial heat transport over the past 20 years. We note that this does not

336 preclude the possibility of strong but opposing trends in atmospheric and oceanic transport. In

337 contrast to CERES, none of the ERA5 hemispheric and global mean trends in TOA radiation are

338 significant at the 95% level (Table 1). Monthly anomaly standard deviations from ERA5 differ by

339 −22% to −7% relative to CERES. Accordingly, ERA5 monthly anomalies track CERES (Fig. S1),

340 but systematic differences are apparent in ASR and −OLR prior to 2003, and in ASR and NET

341 after 2012. Systematic differences between ERA5 and IFS AMIP for ASR and NET are also

342 apparent after 2012 (Fig. S2). This is likely due to changes in the input data stream in ERA5. After

343 removing the trends in the hemispheric and global monthly mean anomaly time series, the

344 correlation coefficient between ERA5 and CERES is 0.80 for ASR and 0.9 for −OLR and NET.

345 Anomaly standard deviations for IFS AMIP are weaker than ERA5 Forecasts and CERES, but

346 trends are in better agreement with CERES, albeit much smaller in magnitude.

347 To examine the robustness of the CERES trends, we compare SH, NH and global trends

348 between CERES instruments flying aboard the Terra and Aqua satellites (Fig. 2). The CERES data

349 products in this comparison are the SSF1deg-Terra and SSF1deg-Aqua products, which are used

15

350   as input to CERES EBAF (Loeb et al., 2018a). Importantly, in-orbit calibration adjustments with

351   time for CERES instruments on Terra and Aqua are entirely independent of one another. The

352   CERES Terra net TOA flux trends as a function of record length from 03/2000 onwards for SH,

353   NH and global (Figs. 2a-c) show large fluctuations for record lengths shorter than ten years due to

354   internal variability, but patterns of change remain fairly stable for longer record lengths. Global

355   and NH trends exceed the 95% significance level for record lengths greater than 12 years, while it

356   takes 17 years in the SH. Trend differences between Terra and Aqua are smaller than 0.05 Wm^{-2}

357   per decade and fall within the 95% significance level for 07/2002-02/2020 (Figs. 2d-f). The Terra

358   ASR trends (Figs. S3a-c) decrease rapidly with record length early in the record but begin to

359   increase after the record length reaches 14 years, which corresponds to when the Pacific Decadal

360   Oscillation shifted from negative to positive (Loeb et al., 2021). ASR trends from Terra and Aqua

361   are within 0.04 Wm^{-2} per decade of one another for the full period, and remain below the 95%

362   significance level for most shorter record lengths (Figs. S3d-f). Similarly, −OLR trends from Terra

363   and Aqua differ by 0.06 Wm^{-2} per decade of one another, which is also within the 95% significance

364   level (Figs. S4d-f).

365   Further validation of the CERES record is provided in Loeb et al. (2021), who compared

366   CERES EBAF variations in global mean net TOA flux with estimates of planetary heat uptake

367   from in situ data for mid-2005 to mid-2019. The in situ data used is derived by an inventory of the

368   rates of changes of energy stored in all components of the climate system, with the primary

369   contribution from differences of overlapping annual 0–2,000 m ocean heat content anomalies from

370   Argo float profiles. As shown in Loeb et al. (2021), the trend in the difference between the CERES

371   and in situ data is 0.068±0.29 W m^{-2} $decade^{-1}$, which is similar in magnitude to the comparison

372   between CERES Terra and Aqua. Independent analyses of the CERES data by Stephens et al.

373　(2022) and Datseris and Stevens (2021) confirm our findings. Additionally, Hakuba et al. (2021)

374　use a combination of altimetric and gravimetric observations from GRACE to find a similar trend

375　in EEI. These results stand in marked contrast with Matthews (2021), who claim that there are

376　"spurious calibration drifts" in the CERES record based upon an analysis of lunar reflectance

377　measured by CERES. A direct comparison between the adjusted CERES Terra reflected SW

378　values proposed by Matthews (2021) and the official CERES SSF1deg Ed4.1 product reveals that

379　Matthews (2021) made the largest "corrections" to the CERES record (reaching -0.8 Wm^{-2}) prior

380　to when CERES Terra even started making lunar observations in 10/2002 (Fig. S5a). If we restrict

381　the comparison only to dates when CERES scans of the moon exist (Fig. S5b), there is virtually

382　no trend difference between the two records (trend difference of -0.012 Wm^{-2} per decade). The

383　CERES lunar data thus confirms that CERES onboard calibration sources are performing

384　nominally.

385　**4.2 Within-Atmosphere Transport**

386　　Trends in TEDIV for 2000/03-2020/02 from ERA5 Analysis, ERA5 Forecasts and IFS

387　AMIP are provided in Figs. 3a-c. Regions with positive TEDIV trends correspond to increasingly

388　divergent lateral energy fluxes, and negative trends correspond to convergent fluxes. The trends

389　based on ERA5 forecasts and IFS-AMIP are similar to those from ERA5 Analysis over ocean,

390　suggesting that the ERA5 Analysis patterns are not a spurious signal from changes in the observing

391　system. All three results show that the magnitudes of TEDIV trends generally exceed those for net

392　TOA flux (Figs. 1a-c). Large positive trends in TEDIV are observed over the eastern Pacific Ocean

393　to the north and south of the Intertropical Convergence Zone (ITCZ), where trends are weakly

394　negative but intensify towards the west over the Maritime Continent. Trends over the Indian Ocean

395　and North Atlantic are generally negative, except over the Gulf Stream, where a strong positive

396   trend is apparent in all three results. Except for the area of positive TEDIV trends stretching from

397   the Barents and Kara Seas, trends over the Arctic Ocean are generally negative, but the magnitude

398   of the trends differs between these three results, with ERA5 forecasts showing the strongest

399   negative trends. Over the Barents and Kara Seas, the increase in divergence is likely due to sea ice

400   loss, which leads to enhanced surface-to-atmosphere heat flux and divergence of energy.

401   Over land, trends for ERA5 analysis are notably greater in magnitude compared to both

402   ERA5 forecast and IFS-AMIP. This points to a greater uncertainty associated with TEDIV derived

403   directly from atmospheric profiles over land. Before computing TEDIV, we perform a vertically

404   uniform correction to the winds to achieve mass conservation. As such, there is no correction for

405   errors in the vertical structure of the wind divergence (as the vertical error structure is hard to

406   estimate), which over topography are likely larger (also arising from numerical noise). TEDIV

407   also contains vertical covariances between atmospheric energy and wind divergence (i.e., the

408   vertical error structure of the wind divergence will project on TEDIV). Since the wind divergence

409   errors likely have trends as well (e.g. from changes in the observing system), we see noisy trend

410   patterns in TEDIV over land. While a substantial fraction of the noisy patterns seen from the ERA5

411   fields is related to numerical noise over topography, some of the non-zero trends over land are

412   similar in ERA5 analysis and ERA5 forecasts (e.g. over central Africa), which suggests spurious

413   jumps in the observing system in that area affecting both analyses and short-term forecasts. Some

414   of the features of TEDIV trends over land may also be realistic and balance observed trends in net

415   TOA flux, such as the negative trends over northern China (compare Figs 3b and 1a).

416   Despite large regional trends in TEDIV, hemispheric average trends are near zero for

417   ERA5 Analysis (Table 2). Global TEDIV trends based on analyses should be exactly zero. This is

418   not the case for ERA5 forecasts since the effect of assimilation increments are not included. Global

419   trends in IFS-AMIP TEDIV should also be close to zero since the model conserves energy (to a

420   relatively high degree).

4.3 Surface

422   Trend maps of F_S using the Inferred method (Eq. 1), ERA5 forecasts and IFS AMIP are

423   provided in Figs. 4a-c. In the latter two cases, F_S is determined from the sum of R_S, H_L, and H_S.

424   Comparing Figs. 3a and 4a, it is evident that regional trend patterns and magnitudes in F_S are

425   mainly determined by those in TEDIV. This is consistent with what previous studies have shown

426   for spatial patterns in climatological mean F_S (Liu et al. 2020; Mayer et al. 2017; Trenberth and

427   Fasullo 2017). As a consequence, trends for the Inferred method over land are largely spurious

428   (see Section 4.2).

429   Over ocean, large-scale patterns of surface flux trends from the three methods are similar

430   over the Southern Ocean, Southern Indian Ocean, Barents Sea, and the Kuroshio Current and Gulf

431   stream. Trends over the Gulf Stream are particularly noteworthy, as all three results show large

432   negative trends, implying increased surface-to-atmosphere heat flux. In this region, the

433   climatological mean F_S is also strongly negative since the atmosphere is supplied energy from

434   warm water masses transporting energy poleward (Trenberth and Fasullo, 2017; Mayer et al.,

435   2021). We also find large negative trends for Inferred (Fig. 4a) and ERA5 forecasts (Fig. 4b) over

436   the East Pacific off of North and South America and a line of positive trends along the equatorial

437   Pacific stretching from the Maritime Continent to Central America. All three products show

438   significant positive trends in the Atlantic between the equator and ~40N. The trends are generally

439   more pronounced for Inferred than for ERA5 Forecasts. In contrast, this trend pattern is less

440   evident for IFS AMIP (Fig. 4c), which entirely misses the positive trends along the equator.

441   In order to further decompose trends in F_S in terms of radiative and non-radiative

442   components, we compute trends in net total radiative flux at the surface (R_S) from CERES (Fig.

443   5a) and determine the "inferred" surface turbulent flux (Q_S) trends based upon Eq. (2) in Fig. 6a.

444   These are compared with regional trends in R_S and Q_S for ERA5 Forecasts (Figs. 5b and 6b). In

445   Fig. 6b, Q_S is obtained directly from the sum of H_L and H_S. While the trend patterns in R_S are

446   similar between CERES and ERA5 Forecasts, their magnitudes are quite different. Large

447   differences are evident over the west tropical Pacific Ocean, where ERA5 Forecasts shows large

448   positive trends that are absent in CERES. Regional trend patterns in Q_S are similar over ocean, but

449   the inferred method produces generally larger values. There is good agreement over the eastern

450   Pacific off the west coast of the Americas, where trends are predominantly negative. Trends in Q_S

451   are generally much larger than those in R_S, suggesting a dominant role for surface turbulent heat

452   flux over net surface radiation at regional scales.

453   Trends in surface turbulent flux from the SeaFlux V3 (Roberts et al., 2020) and OAFlux

454   V3 (Yu and Weller, 2007) products for 08/2002-07/2018 (Figs. S6a-b) are generally in poor

455   agreement everywhere. The lack of agreement is surprising since SeaFlux and OAFlux are

456   dedicated surface turbulent heat products. According to Robertson et al. (2020), trends from these

457   products are less reliable due to problems with wind speed retrievals from Special Sensor

458   Microwave Imager/Sounder satellite sensors and excessive upward trends in Optimal Interpolation

459   Sea Surface Temperature (OISST) data.

460   **4.4 Within Ocean**

461   A benefit of ocean reanalysis is that it provides continuous coverage of the global oceans

462   and therefore can resolve higher frequency variability of ocean heating rate than methods that rely

463   primarily on in situ data like Argo. We compare ORAS5, ORAS6.1 and ORAS6-ctrl global

464 monthly anomalies in full-depth global ocean heating rate for 03/2000-02/2020 (Figs. 7a-c) and

465 the hemispheric and global averages, anomaly standard deviations and trends (Table 3). Anomalies

466 for ORAS5 and ORAP6.1 are similar and show a correlation of 0.5. In contrast, ORAP6-ctrl shows

467 much weaker variability than the other two reanalyses, with a monthly standard deviation that is

468 38% smaller than ORAP6.1, and a correlation with ORAP6.1 of only 0.31. This implies that

469 assimilating more data significantly increases higher-frequency variability. ORAP6.1 shows a

470 sudden decrease around 2005 (Fig. 7b) that is not apparent in ORAS5 or ORAP6.1-ctrl. This dip

471 causes the trend in ORAP6.1 for 07/2005-12/2019 (Table 4) to be much larger than for 03/2000-

472 02/2020 (Table 3). The dip in ORAP6.1 is likely caused by the model bias correction method.

473 Prior to 2005, ORAP6.1 heating rates are similar to ORAS5 but ocean temperatures are much

474 warmer than ORAS5 in the Southern Ocean. When Argo data are assimilated, the ORAP6.1 data

475 assimilation increment cools the ocean, causing a sudden decrease in ocean heating rate around

476 2005. This problem illustrates one of the greatest challenges in ocean reanalyses: how to balance

477 the temporal consistency of the model simulation with the increased accuracy of the state

478 estimation in the data rich periods. This underscores the need for improved treatments of model

479 error in reanalyses.

480   Agreement among global annual variations in CERES net TOA flux and ocean heating rate

481 for the three ocean reanalyses, Argo-only, and combined Argo and satellite altimetry data

482 (Argo+SA) is mixed (Figs. 8a-e). Of the three reanalyses (Figs. 8a-c), ORAP6-ctrl provides the

483 best agreement with CERES prior to 2013. After 2013, ORAP6-ctrl ocean heating rates are smaller

484 than those for ORAS5 and ORAP6.1, which show better agreement with CERES for that period.

485 This suggests that surface forcing and SST information alone are sufficient to estimate ocean

486 heating rate variability during some periods, but in other periods subsurface information may be

487   necessary. When only Argo data are considered, annual variations are very noisy (Fig. 8d). The

488   variability is much greater for 0-2000 m than 0-700 m, a finding also noted in Trenberth et al.

489   (2016). The noise is significantly reduced when Argo and satellite altimetry data are combined

490   (Fig. 8e). Nevertheless, the Argo-only and Argo+SA global trends are similar to CERES while

491   ORAP5 and ORAP6-ctrl show weaker trends (Tables 1 and 4). As noted earlier, ORAP6.1 trends

492   are much larger due to the discontinuity around 2005.

493   With the exception of ORAP6.1, all of the datasets show larger hemispheric mean ocean

494   heating rates for the SH than the NH for 07/2005-12/2019 (Table 4). Overall, ORAS6-ctrl shows

495   the best agreement with Argo and Argo+SA. For ORAP6.1, the SH heating rate is a factor of 2.5

496   smaller than the NH value, and a factor of 3 smaller compared to the SH values from the other

497   datasets in Table 4.

498   A general consensus amongst all of the ocean datasets is a tendency for larger trends in

499   ocean heating rate in the NH than the SH after 2005 (Table 4), but there is poor agreement on the

500   magnitude of the trends. This makes determination of trends in ocean heat transport derived as a

501   residual between net surface flux and ocean heating rate highly uncertain.

502   **5. Summary**

503   This study uses satellite and atmospheric and oceanic reanalysis datasets to address the

504   following question: *To what extent can we trust observed 20-year trends in different components*

505   *of Earth's energy budget and energy flows within the climate system".* We focus on trends after

506   2000 in TOA radiation, TEDIV, surface flux, and within-ocean heating rate using satellite

507   observations from CERES and different versions of atmospheric and oceanic reanalysis datasets

508   from ECMWF. As the trends are likely influenced by both anthropogenic forcing and internal

509   variability, there is no expectation that these are solely representative of longer term trends.

510   Regional trends in TOA net downward radiation from CERES, ERA5 and IFS AMIP are

511 markedly different over the Eastern Pacific Ocean off of North America, where large increases in

512 SST have been observed during the CERES period. Whereas CERES observes large positive

513 trends associated with a reduction in low cloud cover, ERA5 shows negative net TOA flux trends

514 throughout most of the Eastern Pacific Ocean region and IFS AMIP shows weaker positive trends.

515 These results suggest that the low cloud response to SST change may be too weak in ERA5 and

516 IFS AMIP. ERA5 and IFS AMIP show better agreement with CERES over the Atlantic off of

517 North America and Europe, the Indian Ocean between 20°-30°S, and over sea ice regions off the

518 coast of Antarctica. Trends are generally inconsistent over the Arctic Ocean, except in areas near

519 the sea ice edge that are associated with steep declines in sea ice concentration. We find that

520 CERES global mean trends appear to be robust based upon multiple lines of evidence, including

521 direct comparisons between CERES instruments on Terra and Aqua (consistent to < 0.1 W m^{-2}

522 decade^{-1}), comparisons with in-situ measurements from Argo and results that use a combination

523 of altimetric and gravimetric observations from GRACE.

524   CERES trends in net TOA flux between the SH and NH are very close to one another,

525 implying an insignificant 0.02 ± 0.1 PW change to the combined ocean-atmosphere cross-equatorial

526 heat transport over the first 20 years of the 21st century. ERA5 and IFS AMIP also show

527 insignificant hemispheric trend differences, but their SH, NH and global mean trends are smaller

528 than CERES. Surprisingly, ERA5 climatological average net TOA fluxes are approximately half

529 as large as CERES in the SH and more than nine times larger in the NH, while the global mean

530 difference is only 0.05 Wm^{-2}. The ERA5 and IFS AMIP hemispheric asymmetries in mean net

531 TOA flux imply a NH-to-SH cross-equatorial heat transport by the ocean-atmosphere system. That

532 is in marked contrast to CERES, which shows a 0.17 PW SH-to-NH cross-equatorial heat

533   transport, consistent with expectation (Frierson et al., 2013). A possible reason for the inconsistent

534   hemispheric values in ERA5 and IFS AMIP could be due to an unrealistic representation of how

535   clouds are distributed between the hemispheres.

536   We compare TEDIV calculated directly from ERA5 analysed profiles of temperature,

537   humidity and winds (ERA5 Analysis) with TEDIV obtained as a residual between TOA and

538   surface fluxes from ERA5 short-term forecasts and IFS AMIP. Trends based on ERA5 forecasts

539   and IFS AMIP are similar to those from ERA5 Analysis over ocean, suggesting that the ERA5

540   Analysis patterns are not a spurious signal from changes in the observing system. Regional trends

541   in F_S are determined mainly by those in TEDIV, and therefore exhibit similar features. We find

542   consistent negative trends over the Gulf Stream, implying increased surface-to-atmosphere heat

543   flux. Increases surface-to-atmosphere heat flux are also observed over large portions of the eastern

544   Pacific Ocean off the coasts of North and South America. While trend patterns in net surface

545   radiation are similar between CERES and ERA5 Forecasts, large differences are evident over the

546   west tropical Pacific Ocean, where ERA5 Forecasts show large positive trends not observed by

547   CERES. Regional trends in surface turbulent heat flux from an inferred method that uses an energy

548   budget constraint involving CERES and ERA5 analysis data show a similar pattern over ocean to

549   that obtained from the direct sum of sensible and latent heat from ERA5 Forecasts. In contrast,

550   trends from SeaFlux V3 and OAFlux V3 show poor agreement likely because of an excessive trend

551   in OISST input data.

552   Comparisons of monthly ocean heating rates amongst ORAS5, ORAP6.1 and ORAP6-ctrl

553   illustrate some of the challenges associated with ocean reanalysis. The ORAP6-ctrl is a control

554   version of ORAP6.1 that uses the same model setup and atmospheric forcing as ORAP6.1, but

555   only uses SST and SSS nudging at the surface. The difference between ORAP6.1 and ORAP6-ctrl

556 thus indicates the impact of data assimilation on ocean heating rates. While anomalies for ORAS5

557 and ORAP6.1 are similar, variability for ORAP6-ctrl is 38% weaker than ORAP6.1. This implies

558 that assimilating more data significantly increases higher-frequency variability. ORAP6.1 also

559 shows a sudden decrease around 2005 that is not apparent in ORAS5 or ORAP6.1-ctrl, which

560 causes a spurious trend in ORAP6.1. This dip is likely associated with a warm bias in the model

561 that gets corrected after the introduction of Argo data in 2005 by the data assimilation increment,

562 leading to a steep decline in ocean heating rate. Balancing the temporal consistency between the

563 model simulation and introduction of new data in a time series remains a challenge in both ocean

564 and atmosphere reanalysis systems. The impact on trends can be especially large, depending on

565 the magnitude of the model bias and the location within the time series new data are

566 introduced/removed.

567   Global annual variations in CERES net TOA flux and ocean heating rate for the three ocean

568 reanalyses, Argo-only, and combined Argo and satellite altimetry data (Argo+SA) are also

569 compared. Of the three reanalyses, ORAP6-ctrl provides the best agreement with CERES up to

570 2013, while ORAS5 and ORAP6.1 are in better agreement with CERES after 2013. From this we

571 conclude that surface forcing and SST information may be sufficient to estimate ocean heating rate

572 variability for some periods, but other periods may also require subsurface information.

573   All of the ocean datasets except ORAP6.1 show larger hemispheric mean ocean heating

574 rates for the SH than the NH. ORAS6-ctrl shows the best overall agreement with Argo and

575 Argo+SA. For ORAP6.1, the SH heating rate is a factor of 2.5 smaller than the NH value, and a

576 factor of 3 smaller compared to the SH values from the other datasets. All of the ocean datasets

577 show larger trends in ocean heating rate in the NH than the SH after 2005, but there is poor

578   agreement on the magnitude of the trends. Consequently, determination of trends in ocean heat

579   transport derived as a residual between net surface flux and ocean heating rate is highly uncertain.

588

906 Table 2 Average, standard deviation and trend for 03/2000-02/2020 in TEDIV and F_S for the SH, NH and global.
907 Numbers in parentheses correspond to uncertainty at 95% significance level. Bold indicates trend above 95%
908 significance.
