

A global climate model performance atlas for the
Southern Hemisphere extratropics based on regional
atmospheric circulation patterns

Key Points:

- CMIP6 models perform better than CMIP5 models on average
- Southern Hemisphere model ranking similar to Northern Hemisphere ranking
- More complex model versions perform similar to less complex ones

17 **Abstract**

18 The performance of 61 global climate models participating in CMIP5 and 6 is evaluated
 19 for the Southern Hemisphere extratropics in terms of typical regional-scale atmospheric
 20 circulation patterns. These patterns are known to be linked with a number of key vari-
 21 ables in atmospheric physics and chemistry and provide an overarching concept for model
 22 evaluation. First, hemispheric-wide error and ranking maps are provided for each model
 23 and regional details are described. Then, the results are compared with those obtained
 24 in a companion study for the Northern Hemisphere. For most models, the average er-
 25 ror magnitude and ranking position is similar on both hemispheres, ruling out system-
 26 atic tuning towards either of the two. CMIP6 models perform better on average than
 27 CMIP5 models and the interactive simulation of more climate system components does
 28 not deteriorate the results for most model families. Better performance is associated with
 29 higher resolution in the atmosphere, following a non-linear relationship.

30 **Plain Language Summary**

31 This letter provides a survey on the capability of global climate models to repro-
 32 duce the regional atmospheric circulation in the Southern Hemisphere in present climate
 33 conditions. Climate models from the latest model generation are found to perform bet-
 34 ter on average than those of the previous generation and the obtained model ranking is
 35 similar to that found for the Northern Hemisphere in a companion study. While model
 36 performance is found to be generally unrelated to model complexity in terms of covered
 37 climate system components, better results are associated with higher model resolution
 38 in the atmosphere.

39 **1 Introduction**

40 The vast ocean and ice-sheet areas in the Southern Hemisphere (SH) extratrop-
 41 ics are virtually inhabited, but play a key role for the global climate system and are thus
 42 of paramount importance for mankind. In this context, the quasi-persistent circumpo-
 43 lar westerly winds blowing along the open sea channel in the mid-latitudes are of key rel-
 44 evance for several reasons. Partly offset by meso-scale ocean eddies tending to break up
 45 the intense ocean stratification, the westerlies drive the up-welling of carbon and nutrient-
 46 rich deep water and also force the Antarctic Circumpolar Current (ACC), which is em-
 47 bedded in the Meridional Overturning Circulation that in turn governs the low frequency
 48 variability of the global climate system (Abernathay et al., 2011; Speer & Marshall, 2012;
 49 Meredith et al., 2012; Hogg et al., 2017; Zhang et al., 2019). Commonly described by the
 50 Southern Annular Mode, also referred to as “Antarctic Oscillation” (Trenberth, 1979;
 51 Rogers & van Loon, 1982; Thompson & Wallace, 2000), the westerlies have shifted pole-
 52 ward during the last decades while, simultaneously, the Hadley Cell and associated large-
 53 scale subsidence in the sub-tropics have intensified (Thompson et al., 2000; Nguyen et
 54 al., 2015; Fogt & Marshall, 2020). Both anomalies are projected to magnify during the
 55 course of the 21st century in global climate model (GCM) experiments (Deng et al., 2022),
 56 leading to more frequent extreme events like, e.g., droughts (Holgate et al., 2020) or sea-
 57 surface warming events (Duran et al., 2020) whose accumulated effects also alter the mass
 58 balance of the glaciers and ice-sheets in the SH.

59 While Patagonian glaciers are mainly affected by temperature and precipitation
 60 anomalies (Boex et al., 2013), melting into the Amundsen and Bellingshausen Seas is the
 61 main driver of Antarctic continental ice loss (Hughes, 1981; Rignot et al., 2019). The afore-
 62 mentioned poleward shift of the westerlies has led to an enhanced transport of relatively
 63 warm Circumpolar Deep Water, located at intermediate depths below the cold surface
 64 ocean layer, towards the continental shelf of the aforementioned sea areas (Steig et al.,
 65 2012), thereby thinning the ice shelves from below and melting the glaciers and ice streams

66 at their ground lines. Subject to large uncertainties (Rignot et al., 2011), these processes
 67 contribute to global sea-level rise (Fox-Kemper et al., 2021).

68 Over glacial-to-interglacial cycles, the strength and position of the westerlies are
 69 also considered key to variations in the upwelling of carbon-rich Antarctic Bottom Water
 70 (AABW) reservoirs, associated with CO_2 degassing into the atmosphere (Sigman &
 71 Boyle, 2000; Speer & Marshall, 2012). There are indications that strong westerlies located
 72 near the Antarctic continent —well aligned with the ACC—, typically occur during warm,
 73 interglacial periods and enhance the aforementioned process leading to an increase in global CO_2
 74 concentrations. Weaker westerlies located far away from the Antarctic continent and poorly
 75 aligned with the ACC are, in turn, currently discussed to be characteristic of cold, glacial periods.
 76 CO_2 degassing into the atmosphere would be reduced in this case, favouring a net carbon storage in the AABW (Toggweiler et al., 2006;
 77 Gray et al., 2021). Finally, AABW formation itself is also controlled by wind forcing,
 78 namely by southerly katabatic winds blowing down the Antarctic continent, pushing the
 79 sea-ice away from coast and thereby forming coastal polynyas. In these ocean water areas
 80 surrounded by sea-ice, the nutrient-rich upwelled waters are subject to brine rejection
 81 during sea-ice formation that leads to an increase in salinity. Sinking to the ocean bottom is the
 82 consequence, where “preformed” nutrients can thereby accumulate. AABW formation is
 83 particularly productive in the Weddell and Ross Seas and is subject to pronounced low-frequency
 84 variability (Ito & Follows, 2005; Hogg et al., 2017; Silvano et al., 2020).
 85

86 These considerations show that the atmospheric circulation in the SH extratropics, even in confined and relatively small regions such as the aforementioned sea areas,
 87 are relevant for the entire climate system. Consequently, comprehensive GCMs now extensively used in climate research should perform well in this regard.

88 The present study evaluates a large multi-model ensemble from the Coupled Model
 89 Intercomparison Projects 5 and 6 (Taylor et al., 2012; Eyring et al., 2016) in terms of
 90 the models’ capability to reproduce the climatological frequencies of typical and recurrent
 91 patterns of the regional atmospheric circulation in the SH extratropics. To this aim, the Lamb Weather Types method (LWT), also known as Jenkinson-Collison circulation
 92 typing approach (Lamb, 1972; Jenkinson & Collison, 1977; Jones et al., 1993) has been
 93 recently extended for systematic use in the SH (Fernández-Granja et al., 2023) and is
 94 here applied to 61 GCMs from CMIP5 and 6, and to 3 distinct reference reanalyses. The
 95 circulation types obtained from this method are known to correlate with many key variables
 96 in atmospheric physics and chemistry and therefore constitute an overarching concept to describe
 97 regional-scale climate variability. The method is thus complementary to those operating on larger scales used in a previous study (Bracegirdle et al., 2020) and it is a direct answer to the downscaling community’s claim for process-based GCM evaluation based on the regional atmospheric circulation (Maraun et al., 2017; Røste & Landgren, 2022), here tailored to the SH mid-to-high latitudes (Olson et al., 2016; Fita et al., 2017; Charles et al., 2020; Evans et al., 2021). Together with the respective assessment for the Northern Hemisphere (Brands, 2022a), this study completes the picture of GCM performance in terms of regional atmospheric circulation patterns in the extratropics.
 98 Possible model tuning issues to either of the two hemispheres are also discussed.
 99

110 2 Data and Methods

111 The study relies on 6-hourly instantaneous sea-level pressure data from 61 different
 112 GCM configurations participating in CMIP5 and 6, all retrieved from the ESGF data
 113 portals. *Historical* experiments are evaluated and the considered ensemble members for
 114 each GCM are listed in the *get_historical_metadata.py* function available from Brands
 115 et al. (2022). It will be shown that the role of internal model variability does not lead
 116 to substantial changes in the results (see Section 3.1). Since several EC-Earth model ver-

117 sions were found to be favoured when evaluated against ECMWF reanalyses (Dee et al.,
 118 2011; Hersbach et al., 2020) in the companion study conducted over the Northern Hemisphere
 119 (Brands, 2022a), the Japanese 55-year reanalysis (JRA-55) is here used as main
 120 reference dataset for model evaluation (Kobayashi et al., 2015).

121 The Jenkinson-Collison circulation types constitute an objective classification method
 122 based on the subjective approach made by Lamb (1972). This technique, also known as
 123 “Lamb Weather Types” (Jones et al., 1993), groups an instantaneous SLP pattern cen-
 124 tered at a given grid-box into 27 classes depending on the direction of the geostrophic
 125 flow (or lack thereof) and the sign and strength of the vorticity. In addition to the purely
 126 cyclonic and anticyclonic types, there are 8 “purely directional” types—one for each of
 127 the 8 main cardinal directions—and 16 hybrid types characterized by a predominant
 128 flow from one of these directions combined with either cyclonic or anticyclonic conditions.
 129 A detailed description of the LWT method, including the extension to the SH relevant
 130 here, is provided in Fernández-Granja et al. (2023). The corresponding Python code is
 131 available from Brands et al. (2022). The LWT method is here applied in a rolling man-
 132 nner (Otero et al., 2017) looping through all boxes of a regular latitude-longitude grid cov-
 133 ering a spatial domain extending from 30°S to 70°S with a 2.5° resolution. The consid-
 134 ered time period is 1979 to 2005, for which data is available for all applied GCMs and
 135 reanalyses.

136 The LWT method is here said to be applicable for a given region if at least 20 types
 137 occur with a minimum relative frequency of 0.1% (i.e. $n = 39$ occurrences for 27 years
 138 and 6-hourly data) at the corresponding grid-box in the reference reanalysis (JRA-55).
 139 This criterion is fulfilled in virtually the entire study area. Moreover, to ensure that the
 140 regional-scale GCM ranking presented here is robust to a switch in the underlying ref-
 141 erence reanalysis, ERA-Interim is evaluated against JRA-55 just as if it was another GCM
 142 and the obtained error is compared to the errors of the 61 authentic GCMs. If any of
 143 the considered GCMs is found to perform better than ERA-Interim at a given grid-box,
 144 this indicates large observational uncertainties in the corresponding region, leading to
 145 an exclusion of the grid-box from further assessment. Figure 1 shows that all grid-boxes
 146 over the Antarctic continent and adjacent sea-areas seasonally covered by sea-ice have
 147 to be excluded for this reason.

148 For consistency with Brands (2022a) and Brands (2022b), the mean absolute er-
 149 ror (*MAE*) of the climatological relative frequencies of the $n = 27$ LWTs is used as main
 150 error measure at the grid-box scale:

$$MAE = \frac{1}{n} \sum_{i=1}^n |m_i - o_i| \quad (1)$$

151 where m_i and o_i are the relative frequencies of the i^{th} LWT (with $i = 1, 2, \dots, 27$)
 152 from the GCM and reference reanalysis, respectively. Alternative error measures such
 153 as the *Transition Probability Matrix Score* (Fernandez-Granja et al., 2021) have been used
 154 as well, obtaining nearly identical results for the model ranking.

155 To explore the role of internal model variability due to initial conditions uncertain-
 156 ties, up to 18 distinct historical runs per GCM are evaluated for a subset of 13 GCMs,
 157 specified in Supplementary Figure 3. Then, the GCM complexity score proposed in Brands
 158 (2022a) is used, which is proportional to the number of Earth system components taken
 159 into account in the GCM and gives more weight on simulated than on prescribed com-
 160 ponents. This score is put into relation with the spatial median model performance over
 161 the SH in order to explore whether the more complex GCMs perform better or worse
 162 than the less complex ones on average. Finally, the SH results are plotted against the
 163 NH results obtained from Brands (2022a) in order to detect possible tuning efforts to
 164 either of the two hemispheres. For a comparison on equal terms, the NH results were mod-

165 ified by also removing the regions prone to substantial reanalysis uncertainties, as de-
 166 scribed above.

167 3 Results

168 3.1 Regional details

169 Figures 1 and 2 show the GCM ranking patterns based on the MAE for the 61 con-
 170 sidered GCMs, with lower MAE values leading to better ranks and vice versa. The MAE
 171 values themselves are depicted in Supplementary Figures 1 and 2. Hereafter, individual
 172 GCMs will be grouped according to the atmosphere general circulation model (AGCM)
 173 used therein (Brands, 2022b).

174 From these figures, it can be seen that the IFS AGCM family (i.e. all EC-Earth
 175 GCM versions) performs best overall, followed by the HadGAM/UM AGCM family com-
 176 prising the ACCESS and HadGEM GCMs, as well as KACE1.0G. All members of the
 177 HadGAM/UM family except ACCESS1.0 and HadGEM3-GC31-MM have similar error
 178 patterns, with larger errors in the Southern Ocean to the south, southwest and south-
 179 east of the Australian continent. ACCESS1.3, ACCESS-CM2, HadGEM3-GC31-MM and
 180 KACE1.0-G perform relatively poorly to the south and southwest of Cape of Good Hope
 181 and KACE1.0-G additionally performs badly off the east coast of South America. A large
 182 performance gain is observed from CSIRO-MK3.6 to the ACCESS GCM family, i.e. from
 183 the former to the present GCM family developed by CSIRO (see also Figure 3).

184 The GAMIL AGCM family comprising the FGOALS-g2 and g3 GCMs performs
 185 overly poorest in this multi-model comparison. The ECHAM AGCM family, including
 186 all MPI-ESM versions, AWI-ESM-1-1-LR, NESM3 and CMCC-CM, performs slightly
 187 worse than the IFS and HadGAM/UM families, except for MPI-ESM1-2-HR and MPI-
 188 ESM-1-2-HAM performing almost equally well. A particularly poor model performance
 189 is observed for NESM3 along virtually the entire subtropics, extending to the mid-latitudes
 190 in the South Atlantic Ocean, and for AWI-ESM-1-1-LR over the eastern South Pacific
 191 and eastern South Atlantic. The CAM AGCM family comprises the largest number of
 192 GCMs (CMCC-CM2-SR5, CMCC-CM2-HR4, CMCC-ESM2, CCSM4, NorESM1-M, NorESM2-
 193 LM, NorESM2-MM, SAM0-UNICON, TaiESM1, BCC-CSM1.1 and BCC-CSM2-MR)
 194 and yields intermediate to unfavourable ranks in most regions. CMCC-CM, NorESM2-
 195 MM and SAM0-UNICON perform best in this family, yielding very good ranks in spe-
 196 cific regions. CanESM2 comprises the CanAM4 AGCM that is not used in any other GCM
 197 and performs relatively poorly.

198 For the ARPEGE AGCM family shown in Figure 2 (CNRM-CM5, CNRM-CM6-
 199 1, CNRM-CM6-1-HR and CNRM-ESM2-1), the model versions used in CMIP6 (CNRM-
 200 CM6-1, CNRM-CM6-1-HR and CNRM-ESM2-1) perform worse than the well perform-
 201 ing CMIP5 version CNRM-CM5. Surprisingly, this decrease in model performance is par-
 202 ticularly pronounced in the high resolution (HR) version. IFS (EC-Earth2.3, EC-Earth3,
 203 EC-Earth3-Veg, EC-Earth3-Veg-LR, EC-Earth3-AerChem and EC-Earth3-CC) is the
 204 best performing model family in the present study, obtaining very good ranks over a large
 205 fraction of the domain. Model ranks worse than 40 are very rare, except for the ocean
 206 area to the south of Africa in EC-Earth-Veg-LR. The performance of the GFDL-AM AGCM
 207 family comprising GFDL-CM3, GFDL-CM4, GFDL-ESM2G, GFDL-ESM4 and KIOT-
 208 ESM is similar in magnitude to the ECHAM family, with best results overall for GFDL-
 209 ESM4. In case of the GISS-E2 AGCM family, the use of the Russel ocean model in GISS-
 210 E2-R leads to substantially better results than the use of the HYCOM model used in
 211 GISS-E2-H, the configuration of these two GCMs being otherwise equal (Schmidt et al.,
 212 2014), and a further performance increase is obtained by the CMIP6 version GISS-E2.1-
 213 G, comparable to that obtained for the ECHAM and GFDL-AM families mentioned above
 214 (see Figure 3). The most pronounced performance gain from CMIP5 to 6 is obtained for

215 the LMDZ AGCM family (i.e. from IPSL-CM5A-LR and MR to IPSL-CM6A-LR), yielding
 216 a MAE level for IPSL-CM6A-LR comparable to that obtained for the ECHAM and
 217 GFDL-AM families. The MIROC-AM family is prone to very large performance differ-
 218 ences from the better performing versions MIROC5 and 6 to the substantially worse per-
 219 forming versions MIROC-ESM and MIROC-ES2L, which are both more complex (see
 220 Figure 4d). The performance of the GSMUV family decreases substantially from CMIP5
 221 to 6 (from MRI-ESM1 and MRI-ESM2.0) whereas that of the INM-AM family increases
 222 drastically (from INM-CM4 to INM-CM5). Finally, IITM-ESM is one of the worst per-
 223 forming GCMs considered here, with large differences in the results from one region to
 224 another.

225 3.2 Performance Summary and Comparison with the NH results

226 In Figure 3, the hemispheric-wide MAE samples mapped in Supplementary Fig-
 227 ures 1 and 2 are displayed in a single boxplot. Each item describes the error distribu-
 228 tion of a specific GCM in terms of the median (horizontal black line), interquartile range
 229 (IQR , box) and whiskers extending to the full range, except for the outliers lying be-
 230 yond $1.5 \times IQR$ below and above the 2nd and 3rd quartile, respectively. The last four
 231 boxes, depicted in light green, are built upon the joint samples of the more and the less
 232 complex GCMs used in CMIP5 and 6, respectively (outliers are not shown for these sam-
 233 ples). To this end, the GCMs are grouped according to their complexity score obtained
 234 from Brands (2022a) and those obtaining a score ≥ 14 are considered more complex.

235 For both complexity classes, the models used in CMIP6 perform better on aver-
 236 age than those used in CMIP5. The largest performance gains from CMIP5 to 6 are ob-
 237 tained for the FGOALS and IPSL GCMs. However, a performance loss is obtained for
 238 4 GCM groups —ACCESS, CMCC-CM, CNRM-CM and MRI-ESM—, which are 2 groups
 239 more than for the NH results obtained in Brands (2022a). Supplementary Figure 3 shows
 240 that internal model variability does not substantially change the aforementioned results.

241 A comparison between the areal median performance in the SH vs. NH is provided
 242 in Figure 4a and b. Overall, GCM performance is better in the SH than in the NH (panel
 243 a), which may be simply due to the fact that GCMs tend to perform better over the ocean
 244 than over land (Brands, 2022a), the ocean area being much larger in the SH. A close cor-
 245 respondence is obtained for the median error samples of the two hemispheres, particu-
 246 larly if they are log-transformed and standardized separately in order to remove system-
 247 atic differences in their hemisphere-specific shape, magnitude and dispersion (panel b).
 248 Largest deviations from the diagonal are obtained for CNRM-CM6-1-HR, MRI-ESM2,
 249 CMCC-CM2-SR5, CMCC-ESM2 and HadGEM3-GC31-MM, performing better over the
 250 NH, and for CSIRO-MK3.6, KIOST-ESM, GISS-E2-1-G, MPI-ESM1.2-HAM and INM-
 251 CM5, performing better over the SH.

252 A significant non-linear relationship is obtained between the resolution of the AGCM
 253 —here described by the number of grid-points constituting the global 3-dimensional mesh
 254 (longitudes \times latitudes \times vertical layers)—, and the median model performance, obtain-
 255 ing a Spearman correlation coefficient (rs) of -0.49. Higher resolution is associated with
 256 better performance, particularly above a threshold of approximately 1.8×10^7 grid-boxes.
 257 Note that CNRM-CM6-1-HR and CNRM-ESM2-1 are not shown in Figure 4c because
 258 they are out-of-scale due to their very high resolution. Interestingly, the corresponding
 259 link with the 3D resolution of the ocean sub-model is weak ($rs = -0.29$), yet significant
 260 at a test level of 5%.

261 Finally, median model performance over the SH is generally not associated with
 262 model complexity ($r = -0.01$) and, for most model families, the more complex versions
 263 perform at least equally well than the less complex ones (see Figure 4d). The MIROC-
 264 AGCM family is an exception in this sense, since the more complex model versions MIROC-
 265 ESM and MIROC-ES2L, probably due to their low horizontal resolution in the atmo-

266 sphere (T42) (Brands et al., 2022), perform substantially worse than the less complex
267 versions MIROC5 and 6 (T85).

268 4 Conclusions

269 In the present study, 61 different GCMs from CMIP5 and 6 have been evaluated
270 in the SH extratropics excluding Antarctica, focusing on the models' ability to repro-
271 duce the climatological frequency of the 27 Lamb Weather Types, known to be associ-
272 ated with many environmental variables and thus constituting a overarching concept to
273 regional-scale climate variability.

274 While all of the model families performing poorly in CMIP5 have improved con-
275 siderably in CMIP6, most of the families already performing well in CMIP5 have suf-
276 fered a slight performance loss. For most model families, the spatial average performance
277 for the SH is similar to that obtained for the NH (Brands, 2022a), suggesting that sys-
278 tematic model tuning to either of the two hemispheres can be ruled out in general terms.
279 For a small number of specific GCMs, however, substantial performance differences are
280 obtained from one hemisphere to another and the reasons for this should be assessed in
281 future studies. Whereas a higher resolution in the atmospheric sub-model of the consid-
282 ered GCMs is found to be associated with better performance, following an exponentially
283 decreasing relationship, GCM complexity as defined in Brands (2022a) is generally un-
284 related to performance, except for the MIROC-AGCM family, whose more complex ver-
285 sions perform worse than the less complex ones over the SH. This is a promising result
286 since the more complex models are also prone to more error sources. It is also an argu-
287 ment for the use of the more complex models, as they provide a more complete picture
288 of the feedback processes governing the climate system (Séférian et al., 2019; Dunne et
289 al., 2020; Döscher et al., 2021).

290 **Open Research Section**

291 Supplementary Figures 1 to 3 are contained in the Supporting Information (SI) file
 292 to this article, available from GRL's homepage. The Python source code underlying this
 293 study and the GCM metadata archive *get_historical_metadata.py* are publicly available
 294 from Brands et al. (2022) and so is the LWT dataset for the considered GCMs and re-
 295 analyses, retrievable from Brands et al. (2023b). Additional auxiliary material contain-
 296 ing 1) separate pdf files for each error and ranking map, 2) netCDF files containing grid-
 297 box-scale GCM errors and 3) summary csv files listing the model complexity score from
 298 Brands (2022a) as well as the spatial median performance over the SH domain for each
 299 GCM can be retrieved from Brands et al. (2023a).

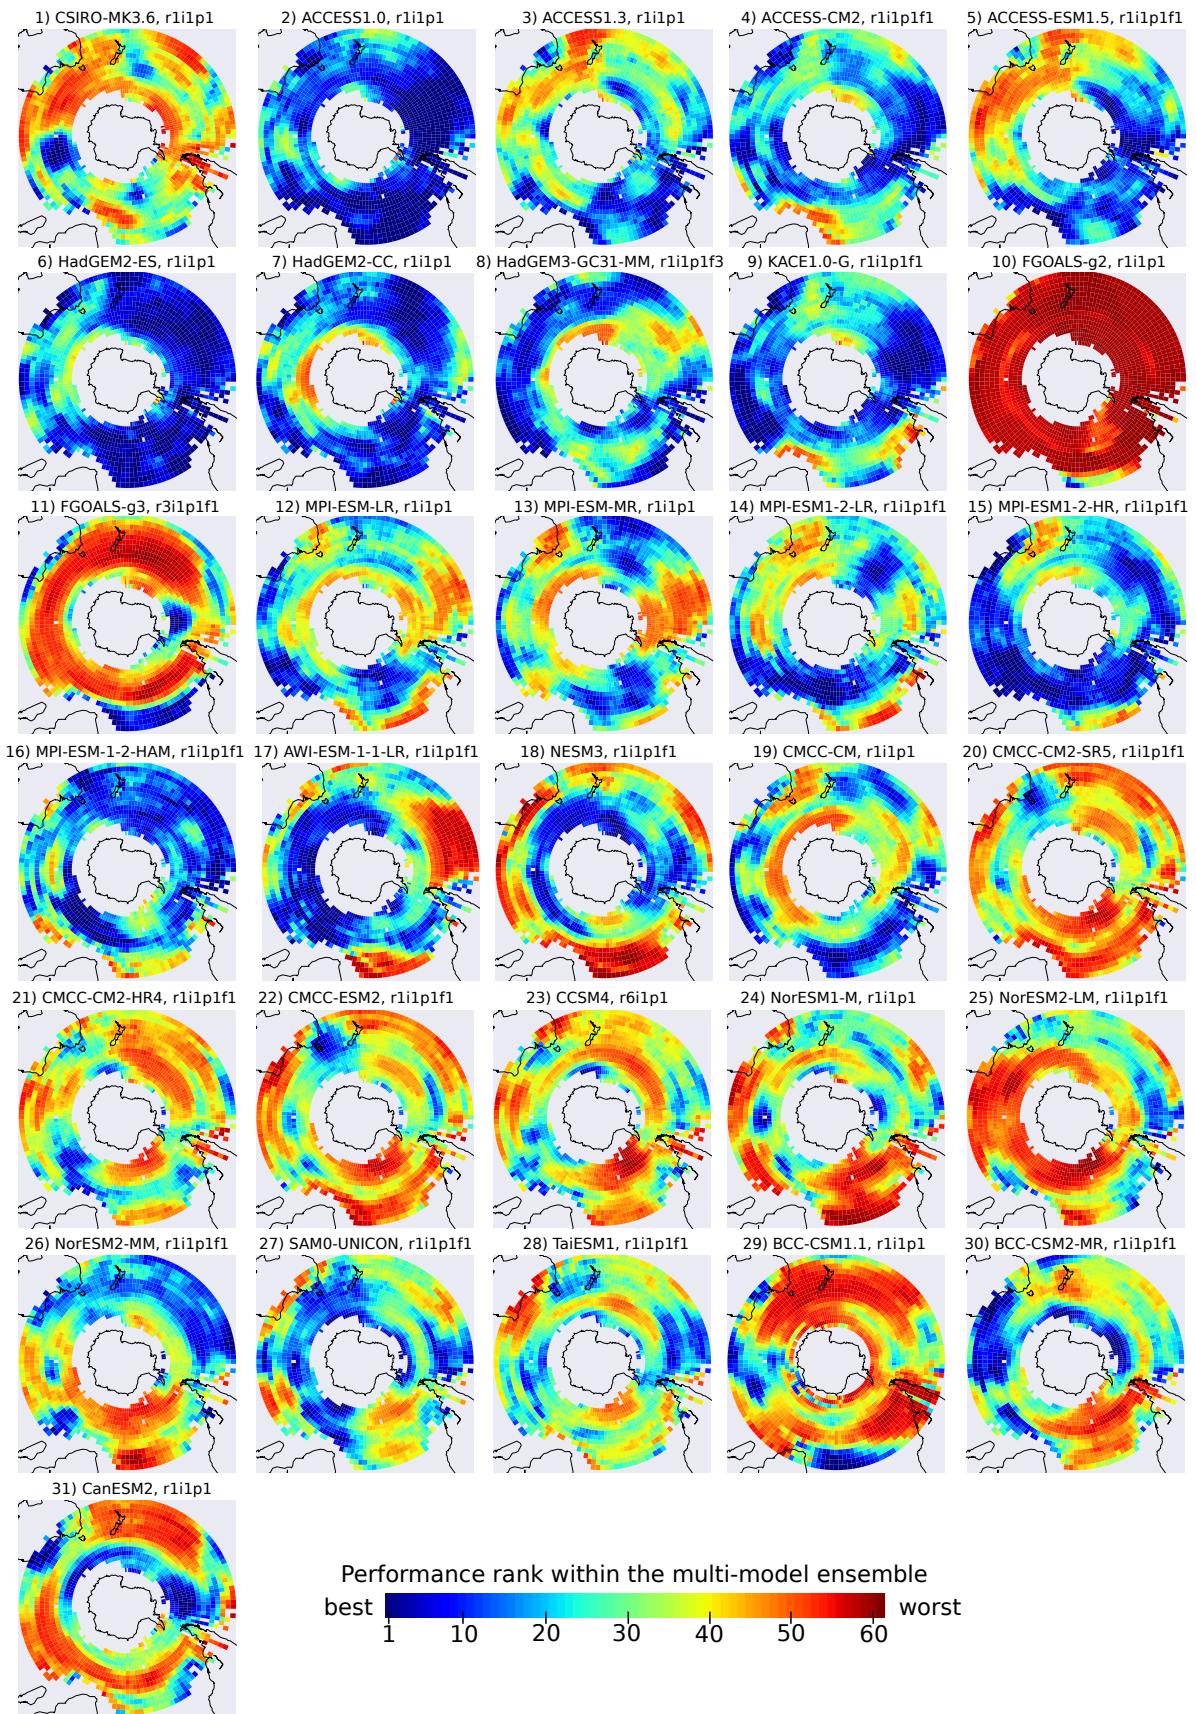

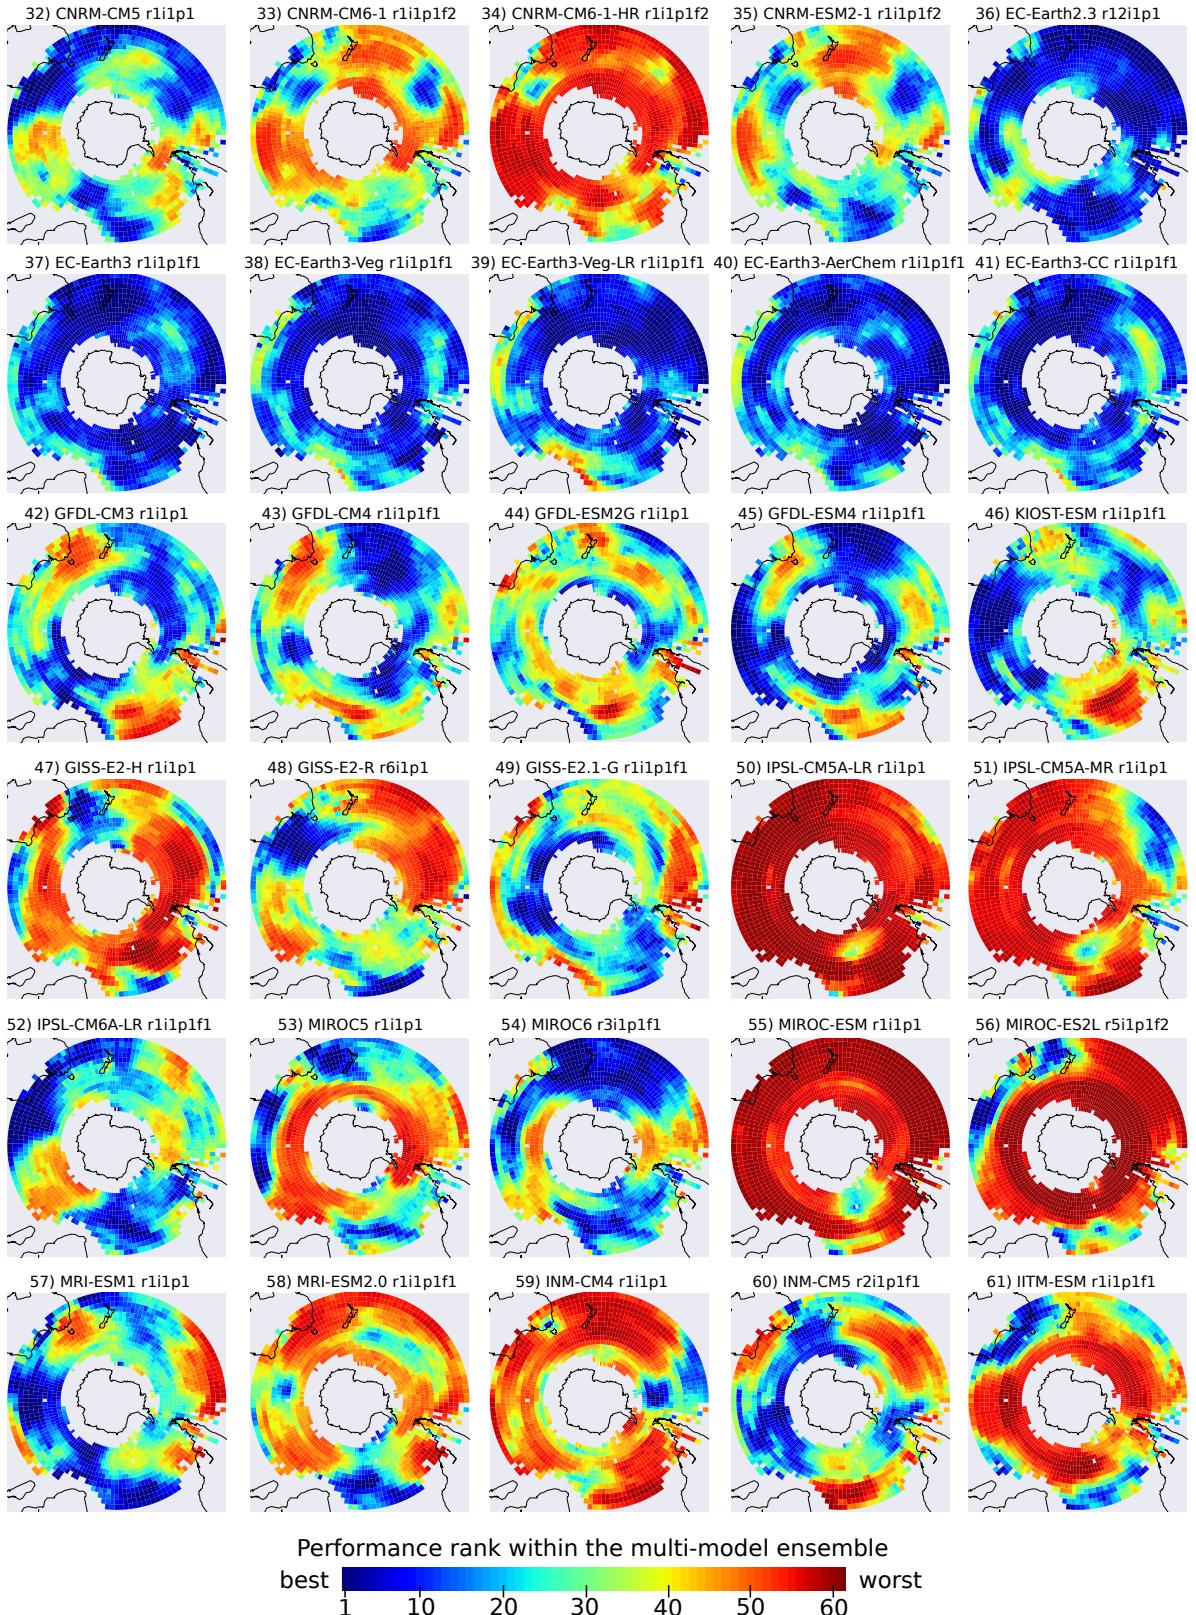

Figure 1. Ranking of the GCMs according to MAE defined in Equation 1, reference: JRA-55, 1979-2005, part 1

**Figure 2.** As Figure 1, part 2

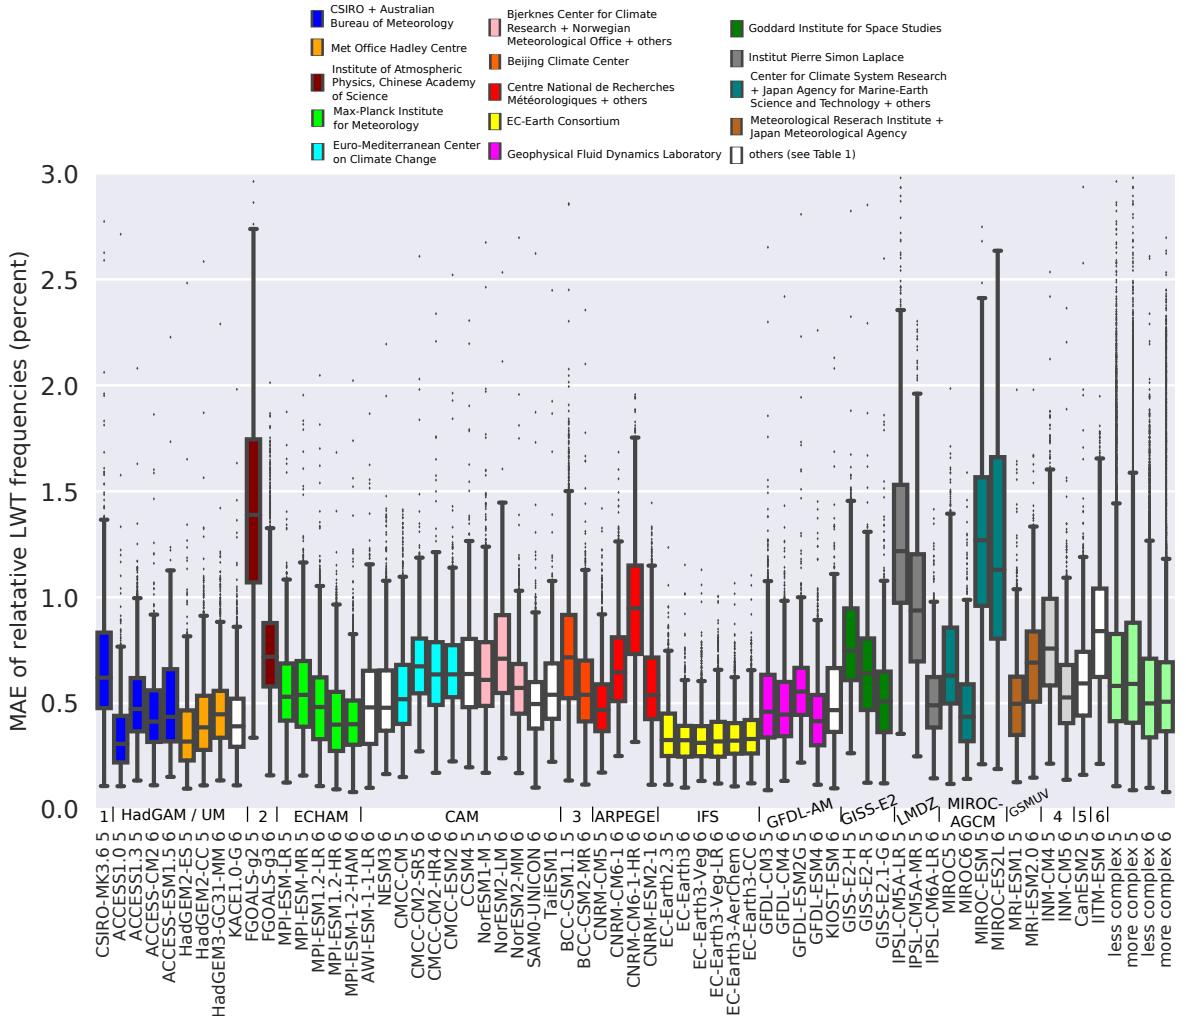

Figure 3. Summary model performance plot. Columns are constructed upon the model-specific, point-wise error values over the Southern Hemisphere as depicted in Figures 1 and 2. The four additional boxplots depicted in light green were built upon the joint error samples of the more and the less complex GCMs used in CMIP5 and 6, respectively. Colours refer to research institutes as listed in the legend. The acronyms of the coupled models, as well as their participation in either CMIP5 or 6 (indicated by the final integer) are shown below the X-axis. Above this axis, the atmospheric component of each coupled model is shown in addition. Results are for the 1979–2005 period and w.r.t. JRA-55. AGCM abbreviations along the X-axis are as defined as follows: 1) MK3-AGCM, 2) GAMIL, 3) BCC-AGCM, 4) INM-AM, 5) CanAM4 and 6) GFS; the names of the remaining AGCMs are indicated in the figure.

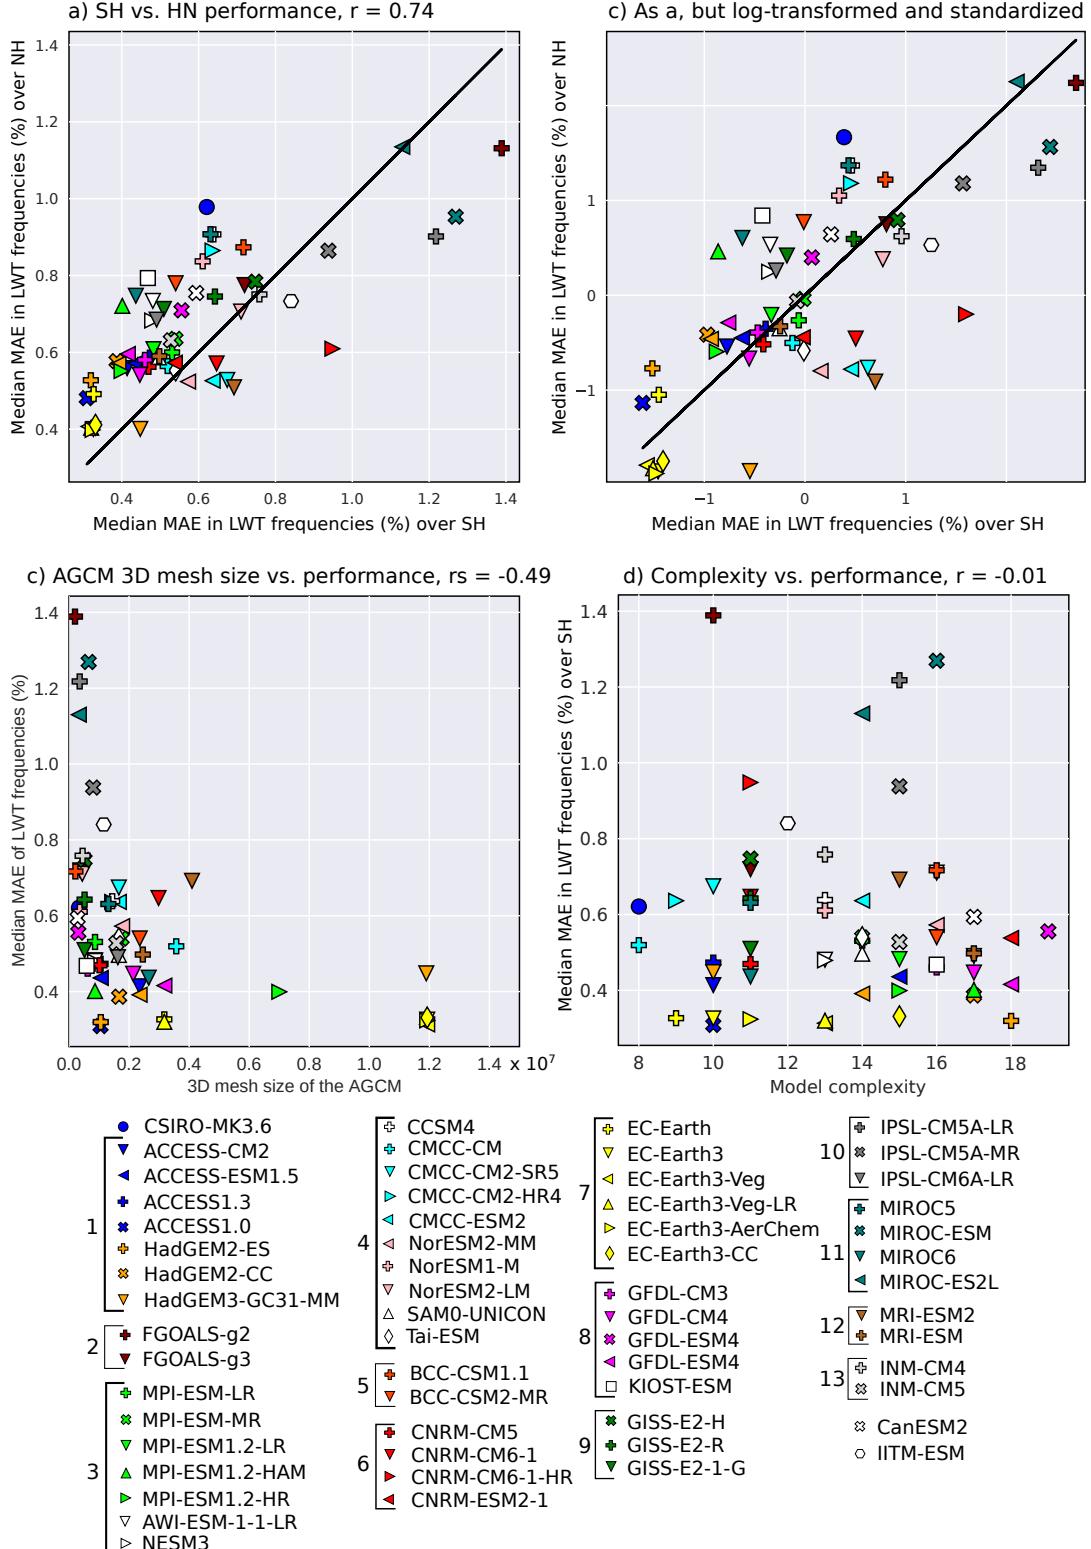

Figure 4. (a) Median model performance per GCM over the SH vs. NH; (b) As a, but for log-transformed and standardized data; (c) 3D mesh size of the AGCM vs. median model performance of the GCM in the SH and (d) Model complexity score proposed by Brands (2022a) vs. median model performance over the SH. AGCM families are indicated as follows: 1) HadGEM/UM, 2) GAMIL, 3) ECHAM, 4) CAM, 5) BCC-AGCM, 6) ARPEGE, 7) IFS, 8) GFDL-AM, 9) GISS-E2, 10) LMDZ, 11) MIROC/CCSR-AGCM, 12) GSMUV, 13) INM-AM
