Abstract

A rare record-breaking extreme rainfall event, the highest amount recorded since 1866, hit Indonesia's capital, Jakarta, in early January 2020. The torrential rainfall was mainly caused by an active cross-equatorial northerly surge (CENS) that occurred concurrently with equatorial waves and Madden–Julian oscillation (MJO). A strong and persistent low-level northerly wind and moisture transport induced by CENS created favorable atmospheric conditions for the formation of deep convection and heavy rainfall over Jakarta. The concurrent occurrences of convectively active phases of equatorial waves (mainly Kelvin, TD-type, and eastward propagating inertia-gravity waves) and MJO during the event further supported the development of heavy rainfall by increasing low-level moisture flux convergence, whereas equatorial Rossby waves contributed indirectly to the increased moisture transport by amplifying cross-equatorial meridional flows toward Jakarta. Together, these large-scale dynamical forcing factors provided a conducive convective environment for the development of mesoscale convective systems and, hence, extreme rainfall over the region.

Plain Language Summary

A record-breaking heavy rainfall event, the highest in the 155-year historical records, hit Indonesia's capital, Jakarta, in early January 2020. The flooding induced by extreme rainfall caused tremendous damage to infrastructure and had significant socioeconomic impacts. This study examines the atmospheric driving mechanisms of this extreme event. We found that strong and persistent low-level winds of the CENS transported moisture toward Jakarta, created favorable conditions for the development of deep convection and heavy rain over the region. The large-scale moisture convergence induced by some types of equatorial waves and MJO further enhanced local moisture and supported the development of convective cells and extreme rainfall. Deepening the understanding of the atmospheric mechanisms driving this event may provide valuable information for forecasting precipitation extremes over Jakarta in the future.

1 Introduction

Jakarta, the capital megacity of Indonesia located in the northwest of Java Island, Indonesia (Fig. 1a), experienced an extraordinary heavy rainfall event in early January 2020. The highest amount reached up to 377 mm (14.83 inches) per day, making it a record-breaking number in observations since 1866. This extreme rainfall subsequently triggered widespread disastrous flooding in Jakarta and its surroundings in the early morning of 1 January 2020, leading to catastrophic losses. It is estimated that at least 173,000 people were evacuated, 66 people died, more than 60% of the residential areas were submerged, and the economic loss reached over US\$700 million (Berlinger & Yee, 2020; Nisa, 2020). Because of the high vulnerability of Jakarta to rainfall extremes, a better understanding of the physical processes of heavy rainfall is needed to establish a reliable extended-range flood forecast system for this region.

Numerous studies have examined the effects of large-scale atmospheric circulation on precipitation extremes and major floods in Jakarta. For example, the major flooding event in February 2007 (the second highest record-breaking precipitation event) was attributed to an intense and persistent cross-equatorial northerly surge (CENS) that created an intensive low-level wind convergence and favorable dynamic conditions for the development of convective cells over the region (Wu et al., 2007; Trilaksono et al., 2011; Hattori et al., 2011). Other studies also showed the potential role of Madden Julian oscillation (MJO) in driving extreme rainfall and major floods in Jakarta (Wu et al., 2007; Aldrian, 2008; Wu et al., 2013; Nuryanto et al., 2019). In particular, Wu et al. (2013) reported that the extreme precipitation that caused a major flooding event in January

2013 was associated with the strong low-level convergence of winds induced by the active phase of the MJO. The enhanced convection induced by MJO contributed to the growth of the mesoscale convective system (MCS) and brought heavy rainfall from its activity over the region (Nuryanto et al., 2019, 2021). Other major Jakarta flooding events in February 2002, 2008, and 2015, were also linked to similar causes, with unusual northerly winds associated with a CENS and the convective phases of MJO (Wu et al., 2007; Aldrian, 2008; Siswanto et al., 2015).

Notwithstanding the importance of CENS and MJO in extreme rainfall events, recent studies have found that equatorially trapped waves, including Kelvin waves, equatorial Rossby waves, tropical-depression (TD)-type waves, eastward propagating inertio-gravity (EIG) waves, and mixed Rossby-Gravity (MRG) waves, also play a major role in organizing tropical convection and triggering torrential rains and floods (Lubis & Jacobi, 2015; Baranowski et al., 2020; Ferrett et al., 2020; Sakaeda et al., 2020; Lubis & Respati, 2021; Latos et al., 2021; Peatman et al., 2021). In general, equatorial waves organize circulation that favors either active or suppressed convection (e.g., Wheeler and Kiladis (1999); Kiladis et al. (2009)), consequently influencing the frequency and intensity of precipitation events. Lubis and Respati (2021), for example, showed that the convectively active phases of Kelvin waves increased the probability of extreme rains over Java by about 30%-60%. Baranowski et al. (2020) also found evidence that Kelvin waves play a critical role in the majority of flooding events in Sumatra. Similarly, Latos et al. (2021) reported that Kelvin waves and equatorial Rossby waves can double the probability of floods and extreme rain events in Sulawesi. Despite clear evidence from these regional studies, it remains elusive whether equatorial waves contributed to the major flooding incident in Jakarta in early January 2020.

This study investigates the atmospheric driving mechanisms of the exceptionally extreme rainfall and devastating floods in Jakarta in early January 2020. We focus on the role of large-scale meteorological drivers in modulating large-scale circulations and moisture transport that favor the development of deep convection and local, extreme precipitation event in Jakarta using in situ measurements, satellite data, meteorological radar observations, and reanalysis data. The current study provides a complete picture of the large-scale meteorological drivers of the major flood in Jakarta in early January 2020.

2 Data

2.1 Satellite Data

The Integrated Multi-satellite Retrievals (IMERG) data from NASA (Huffman et al., 2020) are used for the period of 1 January 2001 to 30 December 2020, with an hourly temporal resolution and on a $0.1^\circ \times 0.1^\circ$ grid. Recent studies have shown that satellite-based precipitation data like IMERG have good capability to observe rainfall variability over the Maritime Continent (Ramadhan et al., 2022) and detect extreme events with short return-periods such as those affected by equatorial waves and MJO (Lubis & Respati, 2021; Schreck, 2021). We also use the Himawari-8 satellite image of IR13 (infrared channel 13) (Bessho et al., 2016) with a spatial resolution of 4 km and a temporal resolution of an hour to observe the development of large mesoscale convective clouds (see Section 3.1).

2.2 C-band Doppler Radar Data

The Gematronik C-band Doppler radar located in Soekarno-Hatta meteorological station (106.6502°E , 6.1669°S , 30 m above mean sea level, with maximum radius coverage of 250 km) is used to derive the high resolution local rainfall field for a period of 31 December 2019 - 1 January 2020. The three-dimensional reflectivity and Doppler velocities are recorded every 8 minutes in a volumetric format consisting of nine plan in-

120 dicator scans from 0.5° to 19.5° with reflectivity values in decibels (dBZ). Radar data
 121 is processed using *wradlib* Python library developed by Heistermann et al. (2013). The
 122 ground clutter caused by non-meteorological factors (e.g., mountains, hills, tall build-
 123 ings) and objects in the air (e.g., aircraft, birds, etc.) are removed by using a texture-
 124 based technique developed by Gabella and Notarpietro (2002). We also apply an atten-
 125 uation correction algorithm to remove random radar noises (Krämer & Verworn, 2009).
 126 The reflectivity data is gridded and displayed as Column Maximum (CMAX) and con-
 127 version of reflectivity (dBz) into rainfall intensity (mm/hr) follows the method used by
 128 BMKG (e.g., Paski et al. (2020)). In this method, the quantitative precipitation estima-
 129 tion (QPE) value is derived from a common Z - R relationship of Marshall et al. (1947)
 130 with $Z = AR^b$, where $A = 200R$, $b = 1.6$, Z is the reflectivity factor, and R is the rain-
 131 fall rate.

132 2.3 In Situ Data, Renalysis, and Other Data

133 We use hourly and daily rainfall measurements from 5 stations located around Jakarta
 134 (namely Kemayoran, Halim Perdana Kusumah, Cengkareng, Tanjung Priok, and Pon-
 135 dok Betung) for the period of December 31, 2019 - January 1, 2020 operated by the Agency
 136 for Meteorology, Climatology and Geophysics of the Republic of Indonesia (BMKG).

137 Meteorological fields from the fifth generation European Centre for Medium-Range
 138 Weather Forecasts (ECMWF ERA5) reanalysis (Hersbach et al., 2020) from January 1,
 139 1980 - December 31, 2020 on a regular 0.25° grid with an hourly temporal resolution are
 140 used to evaluate large-scale synoptic conditions and to analyze moisture transport and
 141 wave analysis during the event. We also uses gridded daily outgoing longwave radiation
 142 (OLR) data from National Oceanic and Atmospheric Administration (NOAA) on a 2.5°
 143 $\times 2.5^\circ$ grid for the period of 1 January 1979 to 31 December 2020 (Liebmann & Smith,
 144 1996) and NOAA Optimum Interpolation (OI) Sea Surface Temperature (SST) V2 data
 145 (Reynolds et al., 2002). SST anomalies are calculated relative to 1971-2000 climatology.

146 3 Methods

147 3.1 Tracking of mesoscale convective system (MCS)

148 A graph theory based algorithm (GTG) (Whitehall et al., 2015) is used for auto-
 149 mated identification and characterization of a large mesoscale convective system (MCS).
 150 The GTG algorithm can handle the complex evolution of the MCS, as it allows MCS to
 151 have multiple cloud element (CE) simultaneously at one time frame. Tracking of MCS
 152 is performed by applying the GTG algorithm to the hourly brightness temperature (TBB)
 153 data from the Himawari-8 satellite. In this study, MCS as a convective system is defined
 154 as contiguous pixels with $TBB < 243$ K and with an area ≥ 2400 km² or a smaller area
 155 where there exists a convective core such there is at least 10 K brightness temperature
 156 range. These criteria must be fulfilled and last continuously for longer than 3 hr (see the
 157 detailed procedures in Whitehall et al. (2015)). Application of the GTG algorithm for
 158 detection of MCSs over the Maritime Continent has been found to be reliable as mul-
 159 tiple merging of convective cells frequently occurs over the region (Nuryanto et al., 2019,
 160 2021).

161 3.2 HYSPLIT Model and Backward Trajectories

162 The mechanisms of moisture transport and the origins of extreme precipitation over
 163 Jakarta in early January 2020 are still uncertain. In this study we employ a backward
 164 trajectory analysis to track the moisture source using a Hybrid Single-Particle Lagrangian
 165 Integrated Trajectory (HYSPLIT) model version 5.1 (Stein et al., 2015). We run the model
 166 every 3 hr starting at 2100 UTC on 31 December 2019 (i.e., the highest peak of precip-
 167 itation event) to generate 72-hr backward trajectories (from 500 to 2,000 m) above the

168 ground in the 50 target points around Jakarta with a horizontal interval of 0.25° deg (see
 169 Fig. 2(k)). We chose this altitude range because water vapor is highly concentrated in
 170 the lower troposphere. In addition, we also calculate relative moisture source contribu-
 171 tions using a similar algorithm proposed by Nie and Sun (2022) (see Text S1 and Fig.
 172 S1 in Supporting Information for a detailed information). The three-dimensional mete-
 173 orological variables, such as specific humidity, winds, and geopotential height used in the
 174 model are obtained from ERA5 reanalysis (Hersbach et al., 2020).

175 **3.3 Filtering technique and wave analysis**

176 To isolate the equatorial wave signals in precipitation and other dynamical fields,
 177 we employ a two-dimensional fast Fourier transformation (2D FFT) filtering technique
 178 (Wheeler & Kiladis, 1999; Kiladis et al., 2009). The wavenumber-frequency domains of
 179 each wave mode used in the filtering technique are similar to Kiladis et al. (2009) and
 180 Lubis and Jacobi (2015) (Table S1 in Supporting Information). Furthermore, to retrieve
 181 the local phases and amplitudes of equatorial waves, we use a similar approach proposed
 182 by Riley et al. (2011) (see Text S2 in Supporting Information). The constructed local
 183 phase diagrams (shown later in Figs. 3b-g) reveals the time-evolution of wave activity
 184 above Jakarta with a reference longitude of 106.5°E . Cool colors (phases 4-6) indicate
 185 enhanced regional convection by the equatorial wave, whereas warm colors (phases 8, 1-
 186 2) correspond to suppressed regional convection.

187 **3.4 Water vapor transport and moisture flux convergence**

188 To understand the underlying mechanisms of equatorial wave and MJO modula-
 189 tion on extreme rainfall, we also calculate vertically integrated water vapor transport (IVT)
 190 and vertically integrated moisture flux convergence (VIMFC) associated with different
 191 types of equatorial waves and MJO. The IVT and VIMFC are calculated from total fields
 192 and then filtered with respect to the different frequency-wavenumber domains (Table S1
 193 in Supporting Information). The IVT is calculated using ERA5 zonal and meridional
 194 winds and specific humidity (see Text S3 in Supporting Information for more details).

195 **4 Characteristics of Heavy Rainfall**

196 Figure 1 shows the characteristics of precipitation during the period from 31 De-
 197 cember 2019 to 1 January 2020, over the flood zone. During this period, heavy rainfall
 198 covered most areas in Jakarta, with higher intensity in the eastern part of the city (Fig.
 199 1a). Based on the averaged in situ data from five stations, the first peak reached 20 ± 14
 200 mm/hour at 1000 UTC on 31 December, and the second peak of rainfall reached 39 ± 28
 201 mm/hour at 2100 UTC on 1 January (Fig. 1b). These results were confirmed by radar
 202 and satellite observations, though there were differences in the amplitude and timing of
 203 precipitation (Figs. 1b-c). In particular, the radar estimates were low compared to the
 204 in situ and satellite observations, possibly due to bias in calibration, correction, and QPE
 205 (e.g., Paski et al. (2020)).

206 Daily rainfall measurements from five meteorological stations in Jakarta indicated
 207 that the highest rainfall accumulation of up to 377 mm per day was recorded at Halim
 208 Perdana Kusumah (PK) Air Force Base in East Jakarta (Fig. 1d). This event was un-
 209 precedented in Jakartas historical rainfall database since 1866 (Fig. S2 in Supporting
 210 Information) and is estimated to have a return period of 300 years (Fig. 1e). This re-
 211 turn period is much longer than the previous major flood event reported in 2015, which
 212 is expected to occur once every 139 years (Siswanto et al., 2015). It is also clear from
 213 the time series of the highest annual rainfall events that changes in the intensity of max-
 214 imum daily rainfall in Jakarta have tended to increase by 15.41 mm/decade (Fig. 1d and
 215 Fig. S2 in Supporting Information).

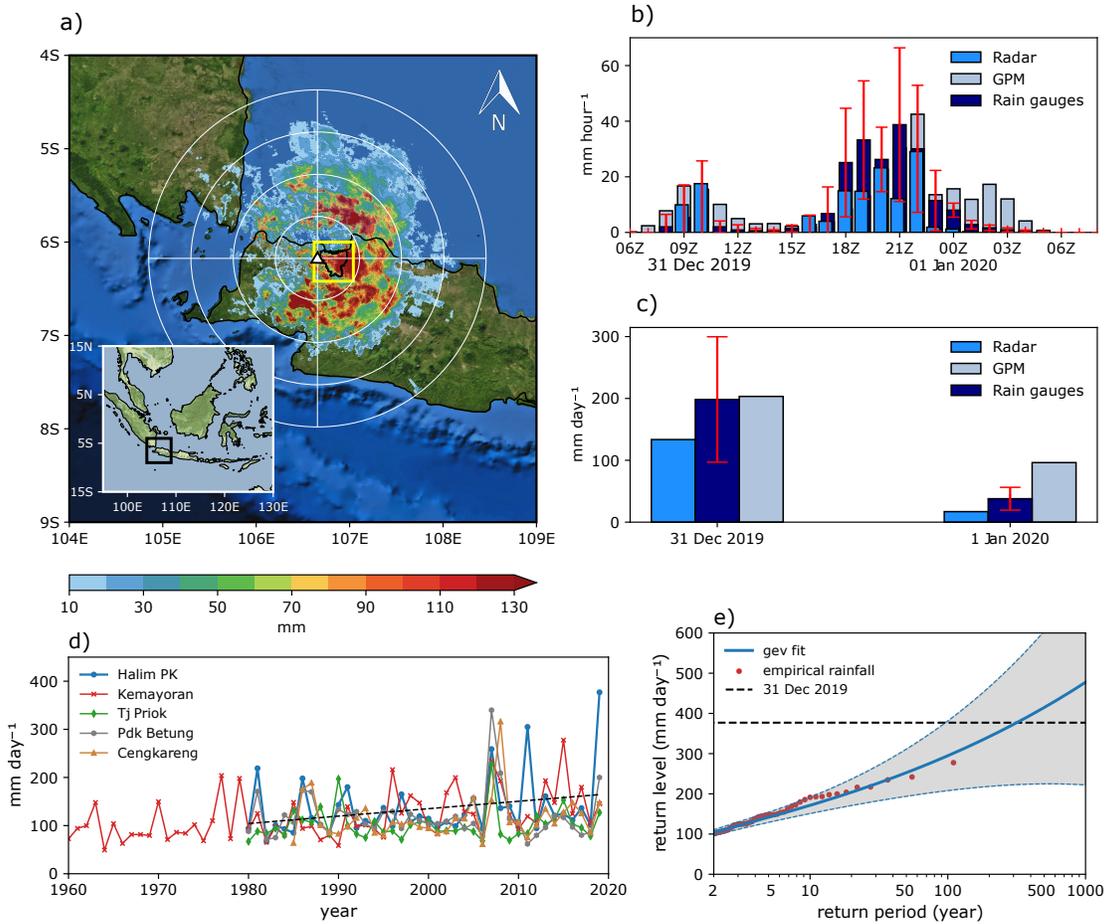

Figure 1. (a) Total precipitation (mm) estimated by C-band Doppler radar located in Soekarno-Hatta meteorological station from 31 December 2019 to 1 January 2020. Location of the city of Jakarta is qualitatively depicted by a yellow box, covering 6.00° - 6.42° S, 106.62° - 107.04° E. (b) Mean hourly accumulated precipitation from GPM satellite, C-band Doppler radar averaged over the box and 5 rain gauge stations. Time is in UTC. (c) Daily mean accumulated precipitation based on GPM satellite, radar, and 5 rain gauge stations. Vertical bars in (b) and (c) denote a standard deviation of the rainfall variation among the stations. (d) Time series of annual maximum daily precipitation (RX1 day) from 5 rain gauge stations from 1960-2019 (see Fig. S1 for the longer records back to 1866). The trend line is calculated for the Halim PK rain gauge station. (e) Return period of Jakarta RX1day for the period of 1960-2019. Blue lines correspond to the GEV fit parameters for 2019 with a 95% confidence interval estimated with a non-parametric bootstrap following Siswanto et al. (2015).

216

5 Large-Scale Atmospheric Drivers of Heavy Rainfall

217

218

219

220

221

222

In this section, we exploit the potential attribution of large-scale meteorological phenomena to the early January 2020 extreme rain and flooding event in Jakarta. Given the fact that during this period, the Indian Ocean Dipole was in a positive phase and the El Niño-Southern Oscillation (ENSO) was in transition to its neutral phase (not shown), other large-scale phenomena beyond the low-frequency variability must have been responsible for driving the extreme event, as we discuss below.

5.1 Occurrence of a cross-equatorial northerly surge (CENS)

Strong and persistent northeasterly winds during the northeast monsoon season played a crucial role in driving the extreme rainfall event in Jakarta in early January 2020 (Fig. 2 and Fig. S3). It is evident that the northeasterly winds over the South China Sea became stronger a few days prior to the episode of heavy rainfall and were classified as an active cold surge (CS) event at 0000 UTC on 31 December 2019 (Fig. 2a and Fig. S3). The cold surge strengthened the northeasterly winds near the surface and the regional topography channeled the flow toward the equator, resulting in cross-equatorial northwesterly flow or CENS at 0800 UTC (Figs. 2a, c-f). At 0900 UTC, the strong cross-equatorial flow infiltrated the northwestern coast of Java (Fig. 2b) and transported an amount of water vapor to Jakarta. This led to heavy precipitation over the region, consistent with the first peak of precipitation at around 1000 UTC (Figs. 2g-h).

As the CENS persisted (Figs. 2a,b), the strong northwesterly winds continued to cross the equator for at least 12 hours, so that the intrusion of water vapor over Jakarta continued intensively after 1000 UTC (Figs. 2 b,e and Figs. 2 i,j). As a result, a massive amount of water vapor was transported by the strong northwesterly winds, leading to more intense precipitation during this period. This is consistent with the second highest precipitation's peak at 2100 UTC on December 31, 2019 (Fig. 1b). From 2300 UTC onward, the CENS began to dissipate (Fig. 2a) and caused a decrease in water vapor transport into the region and hence, reduced precipitation (Fig. 1b). The strong CENS-induced moisture transport during this period is consistent with a large pressure gradient at sea level and surface temperature gradient between the South China Sea and the north Java Sea (Fig. S4).

The intense moisture transport in the presence of the CENS is also confirmed by the backward trajectory of moisture analysis based on the HYSPLIT model (Figs. 2k-l). It is evident that moisture was transported to Jakarta mainly through one route from the South China Sea migrating to the north coast of Java (Fig. 2k). This is also consistent with the transport pathways of IVT during the period of the CENS (color shading). Overall, in the presence of the CENS the South China Sea contributed most of the moisture (59.81%), followed by the southern part of Sumatra Island (26.81%). We also notice a relatively small (2.76%) contribution of moisture source from the Southern Indian Ocean, which might contribute to the local increase in moisture over Jakarta. To summarize, a strong and persistent CENS prior to and during the extreme precipitation event in early January 2020 played a major role in increasing moisture transport towards Jakarta, leading to deep convection and heavy rainfall over the region.

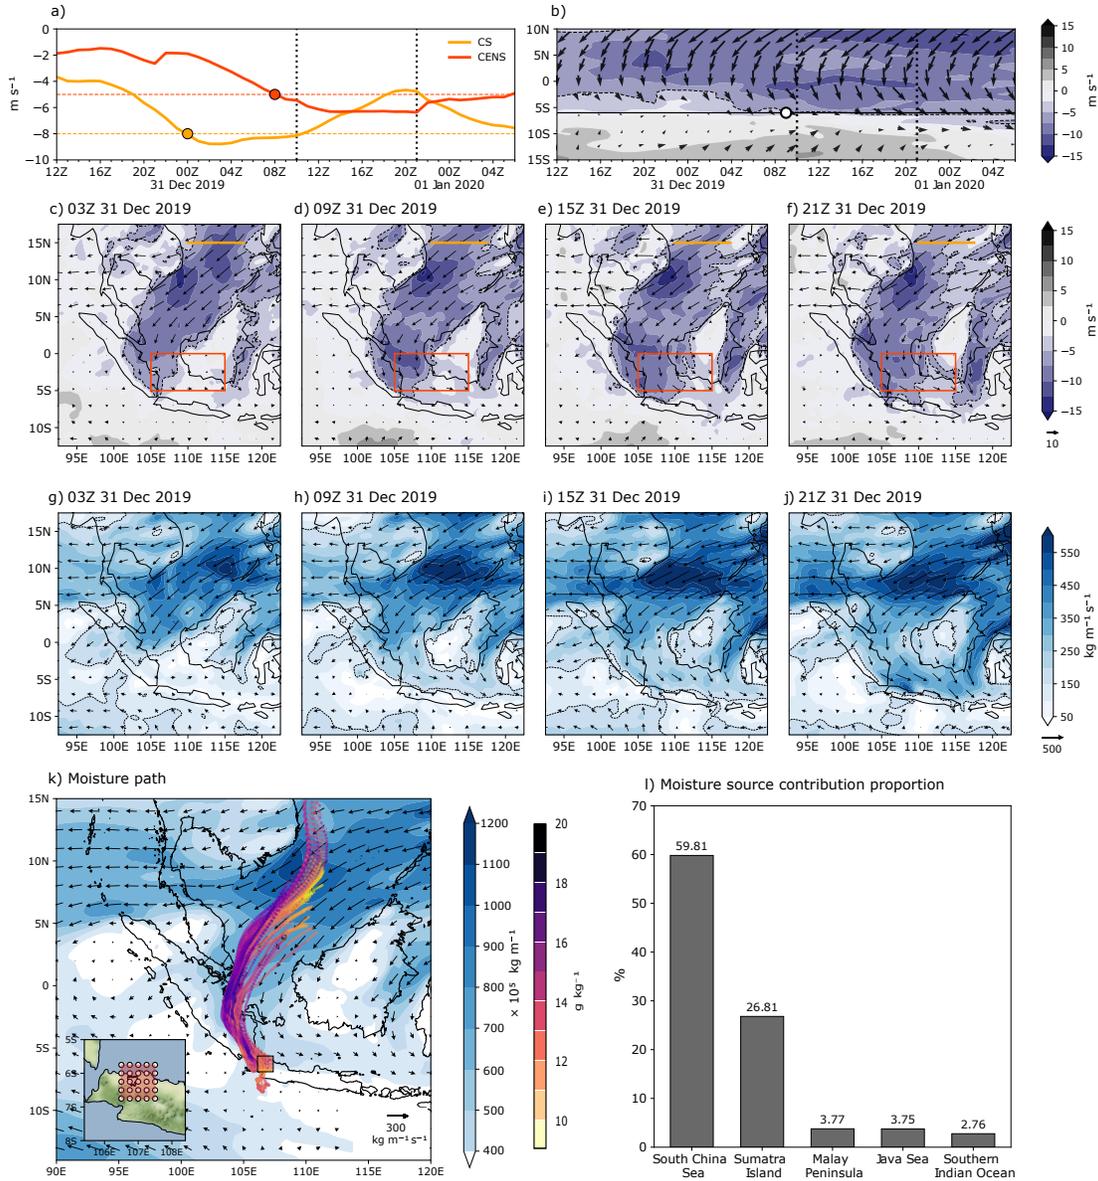

Figure 2. (a) Hourly evolution of CS and CENS indices from 1200 UTC 31 Dec 2019 to 0600 UTC 1 Jan 2020. The red (orange) circle indicates the period when CENS (CS) is active (i.e., exceeding 5 m s^{-1} for CENS (red line) and 8 m s^{-1} for CS (orange line)). The two vertical lines indicate the first and second peaks of the observed precipitation (i.e., at 10Z and 21Z, respectively). (b) Time-latitude cross-sections of the meridional wind component at 925 hPa (shading) and the wind vectors averaged over 106.62° and 107.04°E . The white circle indicates the period when CENS finally intruded into the northern coastline of Java Island (~ 0900 UTC). (c-f) Time evolution of meridional wind component (shading) and horizontal wind vectors (m/s) at 925 hPa from 0400 UTC 30 Dec 2019 to 2200 UTC 31 Dec 2019. The red (orange) rectangular box (line) is the area used for defining CENS (CS). (g-j) As in (c-f) but for the evolution of column integrated water vapor transport (IVT) (shading, $\text{kg m}^{-1}\text{s}^{-1}$) and the corresponding fluxes (vectors). (k) The 72-h backward trajectories of the moisture responsible for the extreme precipitation event. Blue shading indicates the time-integrated IVT for 72-h prior to the period of maximum precipitation (2100 UTC). (l) The relative moisture contributions from the different source regions (see Section 3.2. and text S2 for details).

258 5.2 The role of equatorial waves and MJO

259 In addition to the CENS, the effects of concurrent occurrences of convectively ac-
 260 tive phases of multiple large-scale equatorial waves and MJO also contributed to the de-
 261 velopment of extreme rainfall in Jakarta (Figure 3). It is evident that since December
 262 31, 2019, three types of equatorial wave modes, including Kelvin waves, TD-type waves,
 263 and EIG waves had occurred concurrently with a convective phase of MJO. These con-
 264 current occurrences resulted in significant negative OLR anomalies (enhanced large-scale
 265 convection) over Jakarta (Fig. 3a).

266 More specifically, the convectively active phase of Kelvin waves were observed over
 267 Jakarta on 31 December 2019 and lasted for a few days (Figs. 3a, c), while the TD-type
 268 waves and EIG waves emerged a few days before the end of 2019 and continued until early
 269 January 2020 (Figs. 3a,e,f). Unlike these three types of equatorial waves, the MRG wave
 270 was in its dry phase during the period of extreme rainfall (Fig. 3g) and ER wave activ-
 271 ity had not yet reached Jakarta. Therefore, the MRG and ER waves did not contribute
 272 to the anomalous convective activity during the event (Figs. 3a,d,g). The convective phase
 273 of MJO over Jakarta, on the other hand, had occurred since 27 December 2019, and lasted
 274 until 3 January 2020, as it moved slowly eastward and then transitioned to the dry phase
 275 (Fig. 3a, b). The existence of the MJO above the Maritime Continent is confirmed by
 276 other global MJO indices calculated based on univariate EOF analysis of OLR (Figs. S6a-
 277 c), in which the MJO was in its transition phases from 4 to 5, with a relatively weak am-
 278 plitude. However, its activity over the Maritime Continent was not observed in the mul-
 279 tivariate MJO indices, such as VPM and RMII (i.e. MJO was in weak phase 8, see Figs.
 280 S6d-e). This is because the global multivariate MJO indices tend to be more associated
 281 with the wind circulation than the convection, while the filtered OLR is much more tied
 282 to the convection (cf. Straub (2013); Gottschalck et al. (2013)).

283 The contribution of each wave mode to the anomalous precipitation during the pe-
 284 riod of extreme event is summarized in Fig. 3h. Of the total anomalous precipitation (110
 285 mm/day) on 31 December 2019 observed from NASA IMERG, about $\sim 23\%$ can be at-
 286 tributed to equatorial waves and MJO (see also Fig. S5b for the total precipitation mod-
 287 ulated by these waves and MJO). The Kelvin, TD-type, and EIG waves made a strong
 288 positive contribution to the rainfall anomaly ($\sim 20\%$), while MJO only asserted a weak
 289 positive influence ($\sim 3\%$). The positive contribution of these wave modes and MJO to
 290 the total anomaly are consistent with the increase in low-level convergence of moisture
 291 flux induced by their activities, leading to an enhancement of local convection and hence,
 292 increased precipitation over the region (Fig. 3h).

293 Finally, it is important to note that even though the convective center associated
 294 with the ER waves had not reached Jakarta during the event (Fig. 3a), the large-scale
 295 circulation induced by these waves played a significant role in modulating the cross-equatorial
 296 transport of moisture toward Jakarta (Fig. S7). Our results indicate that the anoma-
 297 lous meridional flow was largely attributed to ER waves (Fig. S7). Therefore, it can be
 298 inferred that the indirect effect of ER waves was to enhance the southerly flow from the
 299 South China Sea toward the Java Sea, leading to the increased moisture transport in-
 300 duced by CENS. In summary, Kelvin waves, TD-type waves, EIG waves and MJO sig-
 301 nificantly contributed to the extreme precipitation event in Jakarta.

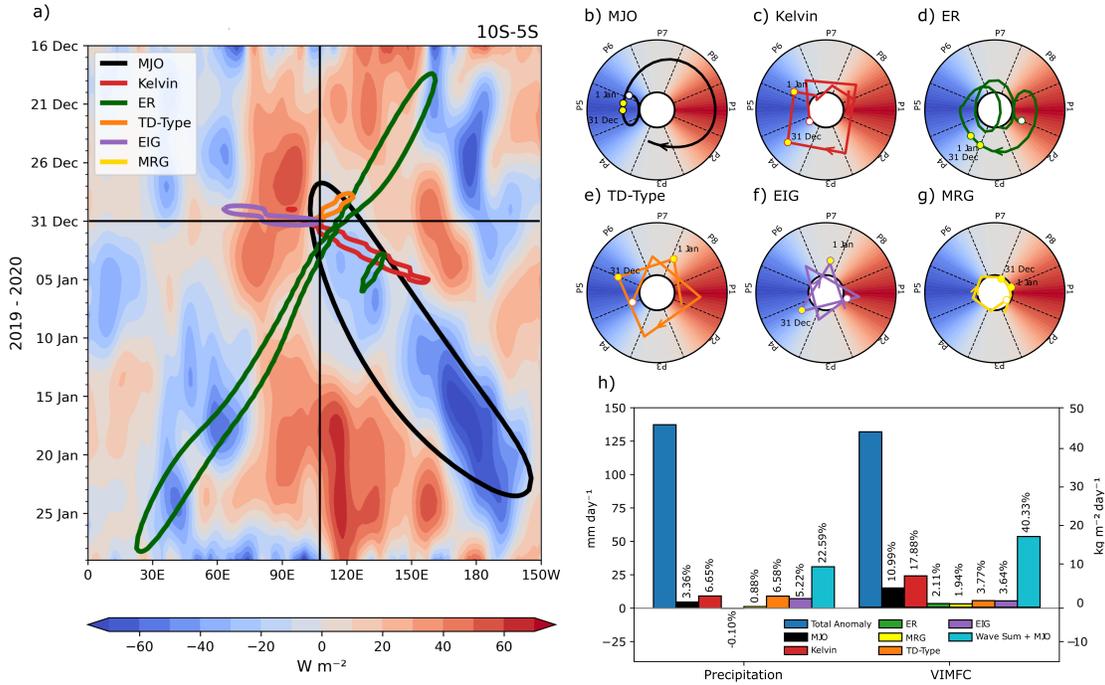

Figure 3. (a) Time-longitude section of OLR anomalies averaged over 10°S-5°S, with an interval of 10 Wm⁻² (color shading). Contour lines show the amplitudes of selected equatorial modes and MJO that have been wavenumber-frequency-filtered (see details in Section 3.3 and Table S1). The contour line for MJO is -17.12 W/m (-2 stddev), for Kelvin waves: -13.48 W/m (-2 σ), for ER waves: -17.58 W/m (-2 σ), for TD-Type waves: -7.56 W/m (-1.5 σ) and for EIG waves: -5.45 W/m (-1.5 σ), where σ is the standard deviation. The vertical line at 107°E marks the location of the city of Jakarta. The horizontal line depicts the period of 31 December 2019. Only the wet phases of the equatorial waves and MJO that occur during the major flood event are shown. (b-g) Local wave phase diagrams of MJO and different types of equatorial waves during the major flood event. The two yellow dots indicate the period of 31 December 2019 and 1 January 2020. The local wave phase diagrams are constructed from the standardized wave-filtered OLR and its tendency centered at 106.5°E (reference longitude). Phases 4-6 (1-2 and 8) are termed as wet (dry) phases throughout the life cycle of waves. (h) Contribution of different types of equatorial waves and MJO on the total daily precipitation and VIMFC anomalies during the Jakarta Flood in 31 January 2019. The percentage (%) is calculated as a ratio of the each filtered-wave anomaly and the total anomaly (blue bar).

5.3 Mesoscale Convective System

The occurrence of extreme rainfall and the corresponding flooding event is often associated with the mesoscale convective system (MCS), which are more favorable in the presence of CENS, equatorial waves, and MJO (Wu et al., 2007; Mapes et al., 2006; Schumacher & Johnson, 2008; Latos et al., 2021). Here, we would like to understand the characteristics of the MCS over Jakarta in the presence of those forcing during the period of the extreme rainfall events.

Figure 4 shows the time evolution of the MCS superimposed with the total precipitation estimated by radar. The MCS over the land began to develop at 0500 UTC on 31 December 2019 from around 7°S (Fig. 4a), over the mountains to the south of Jakarta.

312 At 0600 UTC, the MCS grew stronger and moved northward toward Jakarta (Figs. 4b,c).
 313 This development and its northward propagation was very likely driven by the near-surface
 314 convergence due to the interaction of cloud outflow and warm-moist air near the surface
 315 (Wu et al., 2007; Mori et al., 2018). At around 0900 UTC, the MCS became more ma-
 316 ture and reached Jakarta (Fig. 4d). As the CENS started around 0800 UTC and reached
 317 the coast of Java island at around 0900 UTC (Fig. 2a), the maturation stage of the MCS
 318 during this period was associated with the enhanced moisture induced by the CENS over
 319 the region, which resulted in a stronger updraft and deeper convection (see convective
 320 index development in the presence of CENS in Fig. S8 in Supporting Information). Con-
 321 sistent with the development of the MCS during this time, the first peak of precipitation
 322 was observed over Jakarta at around 1000 UTC.

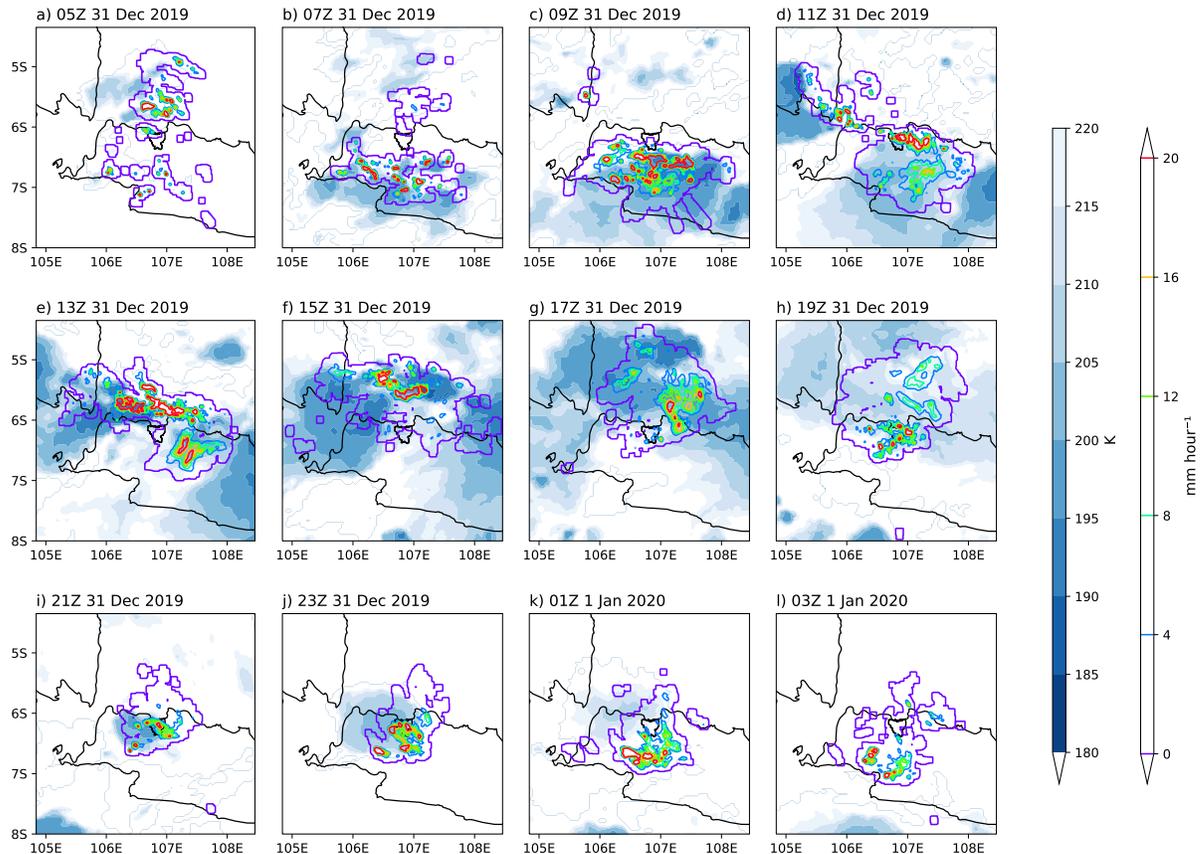

Figure 4. Time evolution of the mesoscale convective system (MCS) calculated based on temperature black body (TBB) retrieved from Himawari satellite (color shading) superimposed with total precipitation (mm) estimated by a C-band Doppler radar (contour lines) from 0500 UTC 31 December 2019 to 0300 UTC 1 January 2020. The color gradation from light to dark blue indicates interior cold cloud with $TBB \leq 221$ K.

323 The MCS continued to migrate northward after 1000 UTC, reaching the Java Sea
 324 at 1300 UTC (Figs. 4e,f). The MCS grew stronger at 1700 UTC over the Java sea and
 325 started to dissipate at 1900 UTC (Fig. 4h). At 2100 UTC, MCS started to grow locally
 326 over the region of Jakarta (onshore) until 2300 UTC (Fig. 2j). This MCS growth could
 327 have been due to the intrusion of the northerly wind into the MCS during the active phase
 328 of CENS (Fig. 2a) and the near-surface convergence lines from the interaction between

329 the cloud outflow and the northerly wind (Wu et al., 2007; Mori et al., 2018). In this case,
 330 CENS acted as an inflow to the preceding MCS, causing it to grow (Mori et al., 2018).
 331 This is consistent with strong and persistent CENS-induced moisture transport and con-
 332 vective activity during this period (Fig. 2a and Fig. S8). At this stage, the MCS brought
 333 rainfall over Jakarta, marking the second peak of the extreme rainfall at around 2100-
 334 2200 UTC. Thereafter, the MCS propagated southward and dissipate at 0300 UTC.

335 To sum up the heavy rainfall over Jakarta in early January 2020 is associated with
 336 MCS. The development of the MCS was closely related to the CENS induced enhanced
 337 northerly wind and moisture transport, which promoted vigorous deep convective sys-
 338 tem over the region. In addition, the convective environment induced by equatorial waves
 339 and MJO (Fig. 3 and Fig. S5), which were present prior to and during the extreme event,
 340 may also potentially support the development of MCS over Jakarta (e.g., Mapes et al.
 341 (2006)). Together, the combined effects of these large-scale forcing factors provided fa-
 342 vorable conditions for the development of MCSs, and hence extreme rainfall over Jakarta.

343 6 Conclusion and Discussion

344 In this study, we have investigated the large-scale atmospheric driving mechanisms
 345 of the torrential rainfall over Jakarta in early January 2020. This extreme event has been
 346 unprecedented in the historical rainfall database in Jakarta since 1866, with a return pe-
 347 riod of 300 years. Our analysis shows that the torrential rainfall event was linked to the
 348 large-scale atmospheric circulation and moisture transport/modulation induced by the
 349 CENS, equatorial waves, and MJO. The key results of our finding can be summarized
 350 as follows:

- 351 1. The extreme precipitation event in Jakarta in early January 2020 was mainly caused
 352 by an active CENS that occurred concurrently with active phases of equatorial waves
 353 (mainly Kelvin, TD-type, and EIG waves) and MJO.
- 354 2. The strong and persistent lower-level northerly wind and moisture transport in-
 355 duced by the CENS created favorable atmospheric conditions for the development
 356 of deep convection and heavy rainfall over Jakarta.
- 357 3. Increasing in low-level moisture convergence induced by the three types of equa-
 358 torial waves and MJO further supported the development of the heavy rainfall over
 359 the region, by contributing up to $\sim 23\%$ to the enhanced local precipitation. On
 360 the other hand, the ER waves contributed indirectly to the enhanced northerly
 361 moisture transport toward Jakarta by strengthening the cross-equatorial merid-
 362 ional flow.
- 363 4. These large-scale dynamical forcing factors together provided a conducive convec-
 364 tive environment for the development of MCSs and hence, extreme rainfall over
 365 the region.

366 Our Lagrangian analysis of moisture sources and pathways confirms that the lo-
 367 cal increase in moisture over Jakarta prior to and during the extreme event was mainly
 368 due to the circulation and transport of moisture associated with the CENS. This is con-
 369 sistent with previous studies, showing that CENS-induced strong low-level vertical wind
 370 shear and moisture allows severe convection to occur over Jakarta (Wu et al., 2007; Mori
 371 et al., 2018). It is also interesting to note that diurnal land convection influences the Mar-
 372 itime Continent response to CENS, leading to the enhanced precipitation over the large
 373 islands (Qian, 2008; Mori et al., 2018). Understanding the interaction between the CENS
 374 and thermally induced diurnal changes in the boundary-layer wind over Jakarta, lead-
 375 ing to enhanced localized convection, requires sensitivity simulations with a high-resolution
 376 general circulation model. This will be the subject of future research.

377 It is noteworthy that although the convectively active phases of Kelvin waves, TD-
 378 type waves, EIG waves, and MJO only played a secondary role in the extreme precip-

379 itation in Jakarta in early 2020, the low-level moisture convergence induced by these waves
 380 and MJO significantly contributed to the enhanced local precipitation. This supports
 381 the findings of recent studies showing the importance of MJO and equatorial waves in
 382 triggering extreme rainfall and flooding events over the Maritime Continent (Baranowski
 383 et al., 2020; Ferrett et al., 2020; Lubis & Respati, 2021; Muhammad et al., 2021; Latos
 384 et al., 2021; Schreck, 2021).

385 In a warmer future climate, models project there will be an increased risk of more
 386 intense, more frequent, and longer-lasting extreme precipitation (Robinson et al., 2021).
 387 Improved understanding of the dynamical mechanisms responsible for such events may
 388 provide some insight into this problem under the warmer climates. In addition, the de-
 389 velopment of novel methodologies for accurate weather predictions could also be achieved
 390 through an improved understanding of the underlying dynamics. These results could,
 391 therefore, be potentially leveraged to improve predictions of extreme weather-driven haz-
 392 ards in Jakarta in the future.

393 7 Data Availability Statement

394 All data used in this manuscript are publicly available. The ERA-5 reanalysis and
 395 SST datasets are publicly available at [https://www.ecmwf.int/en/forecasts/datasets/
 396 reanalysis-datasets/era5](https://www.ecmwf.int/en/forecasts/datasets/reanalysis-datasets/era5) and [https://psl.noaa.gov/data/gridded/data.ncep
 397 .reanalysis2.html](https://psl.noaa.gov/data/gridded/data.ncep.reanalysis2.html). The NASA GPM data may be obtained from [https://doi.org/
 398 10.5067/GPM/IMERGDF/DAY/06](https://doi.org/10.5067/GPM/IMERGDF/DAY/06). Other data including in-situ hourly rainfall, radar re-
 399 flectivity, blackbody temperature of clouds from Himawari-8 satellite, bandpass filtered
 400 data, and HYSPLIT backward trajectory data are available at [https://doi.org/10.5281/
 401 zenodo.6568356](https://doi.org/10.5281/zenodo.6568356). Daily global MJO indices are available at [https://psl.noaa.gov/
 402 mjo/mjoindex/](https://psl.noaa.gov/mjo/mjoindex/).
