9    **Key points：**

10    ● Polyphase deformation and multi-stage pluton emplacement were recognized in the Jiaodong

11    Peninsula

12    ● East China experienced a complex tectonic evolution marked by Late Mesozoic episodic

13    intracontinental extension-contraction

14    ● A multidisciplinary study improves our understanding on the intracontinental deformation under

15    multi-plate convergent system

16    **Abstract**

17    During the Late Mesozoic, East China is characterized by a widespread magmatism, thrusting and

18    folding, extensional doming, strike-slip faulting, and block rotation. The Jiaodong Peninsula provides a

19    key area located in East China to understand the episodic intracontinental extension and contraction,

20    and associated granitoids emplacement. Based on our structural analysis, magnetic fabrics and gravity

21    modeling, polyphase deformation and magma emplacement have been recognized within the

22    Queshan-Kunyushan-Yuangezhuang-Sanfoshan (QKYS) massif of the central Jiaodong Peninsula. A

23    significant Late Jurassic $D_1$ event, developed in the northern margin of the massif, was expressed by a

24    high-temperature, top-to-the-NE shearing. Late Jurassic plutons display magnetic fabrics corresponding

25    to the $D_1$ structural fabrics and several NW–SE-trending feeder zones at depth. These results link the

26    syn-kinematic emplacement of Late Jurassic plutons with regional NE–SW extensional tectonics. At the

27    south of the massif, a lower-temperature, top-to-the-SW contractional deformation ($D_2$) resulted from

28    NE–SW contraction. The $D_3$ shear zone with a top-to-the-WNW kinematics is a rolling-hinge type

29    detachment fault that exhumed the massif, indicating NW–SE regional extension. Finally, Early

30    Cretaceous plutons emplaced into upper crust with a fast cooling rate and formed an inverted drop shape

31    with concentric magnetic foliations and variably oriented magnetic lineations. At the light of the

32    previous geochronological results, the timing of these tectonic events are discussed. The tectonic

33    evolution of the QKYS massif indicates a process from crustal thickening to lithospheric foundering

34    in response to the Late Mesozoic plate convergences.

**1 Introduction**

In typical collisional or accretionary orogens, deformation mainly takes place at plate boundaries and adjacent regions, since the continent interior is considered rigid (Coward *et al*., 1987). However, intensive deformation could develop inside the continent, even though it is far away from plate boundaries (*e.g*., Dickinson & Snyder, 1978; Roure *et al*., 1989; Avouac *et al*., 1993; Chu *et al*., 2012, Chu & Lin, 2018). East China was formed by continental collision between North China Craton (NCC) and South China Block (SCB) at the Early Mesozoic (Mattauer *et al*., 1985; Xu *et al*., 1992; Cong *et al*., 1995; Hacker *et al*., 1998; Faure *et al*., 1999). During the Late Mesozoic, East China is surrounded by multi-plate convergent zones, including Mongol-Okhotsk belt to its north, the subduction zone related to Izanagi Plate to its east and the collisional zone between Lhasa and Qiangtang blocks to its west (Figure 1). At this time, East China is characterized by a widespread magmatism, large-scale thrusting and folding, extensional doming, strike-slip faulting, graben and half-graben basins, and rigid blocks rotation (Lin *et al*., 2003; Otofuji *et al*., 2006; Dong *et al*., 2015 and references therein). It offers a key area to understand the mechanism of episodic intracontinental extension and contraction, and associated magmatism under the multi-plate convergences.

Previous studies that focused on the Jurassic–Cretaceous tectonic evolution of East China have suggested (1) two significant episodes of contractional tectonics during Middle or Late Jurassic– Earliest Cretaceous (Wong, 1929; Chen, 1998; Davis *et al*., 2001; Darby & Ritts, 2002; Davis *et al*., 2009; Faure *et al*., 2012); (2) subsequent Early Cretaceous extensional tectonics, characterized by numerous extensional basins, metamorphic core complexes (MCC) and syn-kinematic plutons (Davis *et al*., 2002; Ren *et al*., 2002; Meng, 2003; Wang *et al*., 2012; Liu *et al*., 2013; Lin & Wei, 2018; Chu *et al*., 2019); and (3) long-term magmatism from 170 to 110 Ma with Late Jurassic (170–150 Ma) and Early Cretaceous (135–110 Ma) magmatic flare-ups (Wu *et al*., 2019). These events have been considered differently by various geologists based on regional unconformities, polyphase deformation, and

62    magmatism, leading to a broad Late Mesozoic tectonic framework of East China. Especially for Late

63    Jurassic–Earliest Cretaceous tectonics, its timing and kinematics remain hotly debated, and the

64    interplay between structure and magmatism is still poorly constrained (Dong *et al.*, 2015 and references

65    therein). More importantly, Early Cretaceous crustal extension results from the "craton destruction";

66    lithospheric foundering/delamination or thermal erosion were suggested to be potential mechanism, in

67    which old and refractory lithospheric mantle is replaced by juvenile and fertile one (Menzies *et al.*, 1993;

68    Xu, 2001; Lin & Wang, 2006; Zhu *et al.*, 2011; Lin & Wei, 2018; Wu *et al.*, 2019; among others). Hence,

69    the Late Mesozoic tectonic evolution helped to understand the mechanism of "craton destruction".

70    In general, granitoids emplacement is controlled by internal dynamics and external tectonism

71    (Bouchez, 1997; Miller *et al.*, 2009; Žák *et al.*, 2013, Lehmann *et al.*, 2013; Paterson *et al.*, 2019,

72    among others), and their subsequent exhumation is commonly related to regional ductile shear zones

73    (Bouchez *et al.*, 1990; Archanjo *et al.*, 2002; Rabillard *et al.*, 2015; Wei *et al.*, 2016; Chu *et al.*, 2019,

74    among others). Hence, the emplacement-exhumation history of granitoids contains significant

75    information on tectonic evolution (*e.g.*, Lin *et al.*, 2013a, Ji *et al.*, 2018a). This history also can be

76    revealed by fabric patterns, shapes at depth, and kinematics of major ductile shear zones at the margins

77    of plutons, which are accessible through structural analyses, anisotropy of magnetic susceptibility

78    (AMS) and gravity surveys.

79    The easternmost part of East China (*i.e.,* Jiaodong Peninsula) is a key area to understand the

80    complex plutonic-tectonic history, because it developed an intensive magmatism, contractional and

81    extensional events, and large-scale gold mineralization during the Late Mesozoic (Li *et al.*, 2019). In

82    this paper, the Queshan-Kunyushan-Yuangezhuang-Sanfoshan (QKYS) massif, located in the central

83    part of the Jiaodong Peninsula (Figure 1), was targeted for the following reasons. Firstly, it comprises

84    Late Jurassic and Early Cretaceous granitic intrusions within their metamorphic country rocks, which

85    experienced a polyphase deformation. Secondly, Late Jurassic and Early Cretaceous plutons were

86  emplaced into middle crustal and upper crustal levels, respectively (Dou *et al*., 2018). Lastly, the

87  crystallization and cooling ages of this massif are already well-defined. Accordingly, we carried out a

88  multidisciplinary study containing structural analyses, AMS and gravity surveys on it, aiming to depict

89  its multiple emplacement and exhumation, the relationship between magmatism and regional tectonics,

90  and finally the Late Mesozoic tectonic evolution and geodynamics of East China.

91  **2 Geological setting of the Jiaodong Peninsula**

92      Jiaodong Peninsula, bounded by the Tan-Lu fault to its west, is situated in the easternmost part

93  of East China (Figure 1). It can be divided into three tectonic units: Jiaobei domain in its northwestern to

94  central part, Northern Sulu domain in its eastern part and Early Cretaceous Jiaolai Basin containing

95  volcanic and clastic rocks to the southwest (Figure 1).

96      The Jiaobei domain contains three metamorphic units. From bottom to top: (1) Neoarchean to

97  Paleoproterozoic meta-granite, gneissic migmatite, granulite with meta-mafic or amphibolite lenses; (2)

98  Paleoproterozoic meta-sedimentary rocks including micaschist, paragneiss, marble and amphibolite; (3)

99  Neoproterozoic weakly to un-metamorphosed terrigenous rocks (Hacker *et al*., 2006; Wan *et al*., 2006;

100 Li *et al*., 2007). Geochronological works reveal that these rocks have Neoarchean-Paleoproterozoic

101 protolith ages with peaks at 2.9, 2.7 and 2.5 Ga and experienced a 1.8 Ga amphibolite-facies

102 metamorphism, belonging to the NCC (Zhao *et al*., 1998; Zhai *et al*., 2000, 2005; Zhang *et al*., 2014).

103     The Northern Sulu domain mainly consists of migmatite, gneiss, quartzite, marble, and

104 decimeter-sized mafic to ultramafic blocks (Figure 1). They display a protolith age of 0.75 Ga and Late

105 Triassic metamorphic ages, suggesting a SCB affinity (Liu & Liou, 2011). Eclogites are enclosed as

106 blocks within these rocks. In particular, the discovery of coesite as inclusions within the melanosome of

107 migmatite and orthogneiss implies that they experienced an ultra-high pressure (UHP) metamorphism

108 during the Late Triassic (Wang *et al*., 1993; Wallis *et al*., 1997). It is well accepted that the UHP rocks

109 formed by the deep subduction of the SCB beneath the NCC; the retrograde metamorphism and

110 migmatization are associated with a Late Triassic extensional tectonics (Faure *et al*., 2001, 2003).

111    Widespread Mesozoic intrusive rocks are exposed in the Jiaodong Peninsula. These intrusions

112 can be divided into four groups according to their ages: (1) Late Triassic syenite; (2) Late Jurassic

113 monzogranite; (3) Early Cretaceous porphyritic granitoid; and (4) Early to Late Cretaceous

114 mafic-intermediate dykes (Guo *et al*., 2005). The Late Jurassic plutons are derived from partial melting

115 of a thickened lower crust, while the Cretaceous plutons and dykes resulted from lithospheric mantle

116 removal, accompanied by asthenospheric upwelling (Yang *et al*., 2008; Goss *et al*., 2010; Zhang *et al*.,

117 2010). It should be noted that the significant Late Mesozoic deformations are mainly distributed at the

118 margins of these Late Mesozoic plutons (Figure 1; Shen *et al*., 1998; Charles *et al*., 2011a; Xia *et al*.,

119 2016)

120 **3 Structural analysis of the QKYS massif**

121    3.1 Litho-tectonic units of the QKYS massif

122    As a part of the Jiaobei domain, the QKYS massif is composed of Late Mesozoic plutons, which

123 mainly trend NNE–SSW, and their country rocks (Figures 2 and 3). Western margin of the QKYS

124 massif is a ductile shear zone that separates the massif from Early Cretaceous volcanic and clastic rocks.

125 Taocun and Mishan faults are considered as its northwestern and eastern boundaries, respectively

126 (Figure 2). To its north and south, the massif is covered by Cenozoic fluvial and lacustrine deposits. The

127 QKYS massif can be divided into four litho-tectonic units: (1) Neoarchean to Paleoproterozoic

128 meta-granite, gneissic migmatite, granulite with meta-mafic or amphibolite lenses; (2) Paleoproterozoic

129 meta-sedimentary rocks including micaschist, paragneiss, marble and amphibolite; (3) Late Jurassic

130 Queshan (Q) and Kunyushan (K) plutons composed of medium- to coarse-grained biotite monzogranite;

131 and (4) Early Cretaceous Sanfoshan (S) and Yuangezhuang (Y) porphyritic granite.

132    The country rocks of these granites include 2.6–2.5 Ga meta-mafic rocks, 2.7–2.4 Ga

133    meta-granites, and metamorphic sedimentary rocks that are considered as deposited at 2.1–1.9 Ga (Liu

134    *et al*., 2017a). Zircons of K and Q plutons have inherited cores (*e.g.*, Guo *et al*., 2005; Zhao *et al*., 2016)

135    and were affected by later thermal event (*e.g.*, Xia *et al*., 2016), resulting in a broad range of ages (163–

136    141 Ma, Figure 4A) for these two plutons. Therefore, we use statistical peak age (153 Ma) as their

137    crystallization ages (Figure 4B). Most parts of the massif have Early Cretaceous $^{40}$Ar/$^{39}$Ar ages (*i.e.,*

138    135–120 Ma), and the older ones (*i.e.,* 219–146 Ma) are present in its southern part (Figure 4C). For the

139    S and Y plutons, they have indistinguishable zircon U-Pb and biotite $^{40}$Ar/$^{39}$Ar ages ranging from 118 to

140    113 Ma (Figure 4C and D).

141    3.2 Bulk architecture and kinematic analyses of the QKYS massif

142    In the QKYS massif, K pluton has an elliptical shape with a NNE–SSW long axis, and

143    irregular-shaped Q pluton is separated into two parts due to late sinistral strike-slip movement of Zhuwu

144    fault (Figure 2). Well-foliated to mylonitic gneiss, schists, marble, and amphibolite are exposed as their

145    country rocks. The K pluton is dominated by isotropic monzogranite in its central part, while clear

146    foliation is present on its NE margin, which is composed of recrystallized quartz aggregates and

147    feldspar (Figure 5A and B). In the western part of the Q pluton, conspicuous mylonitic foliations are

148    well developed. The gently dipping post-solidus foliation is defined by recrystallized quartz grains,

149    rotated K-feldspars, and oriented biotite (Figure 5C). A homogeneous monzogranite type composed of

150    K-feldspar, quartz, plagioclase, and biotite is dominant in the eastern part of Q pluton. The S pluton with

151    a NE–SW long axis intruded into the K pluton and the UHP gneiss, while the Y pluton emplaced along

152    the northern margin of Q pluton (Figure 2). Both S and Y plutons are isotropic (Figure 5D).

153    Based on our structural analysis, the bulk architecture of the QKYS massif is dominated by a

154    Late Mesozoic dome that experienced ductile deformation at its northern, southern, and western

155     margins (Figures 2, 3 and 6). The foliations of orthogneiss and gneissic migmatite between Q and K

156     plutons mainly dip to SE, NW or NE at variable dip angles and contain NW–SE mineral and

157     stretching lineations (Figure 6A).

158        Along the northern margin of K pluton, a solid-state foliation develops, up to a few hundred

159     meters inside the pluton, pointing to the existence of a deformation event. Following the contact

160     between the granite and the country rocks, the granite foliation dips to the N, NE, or NNW with

161     moderate to low dip angles, and changes to E(S)E dips in its eastern part, with a locally NE–SW

162     sub-horizontal mineral lineation (Figures 6B and 7A). Close to the northern margin of K pluton, the

163     orthogneiss shows dominantly NW–SE striking foliations that are parallel to the granite/orthogneiss

164     contact (Figure 6C). Isoclinal folds with axes parallel to the NE–SW mineral and stretching lineation

165     developed in the orthogneiss (Figure 7B). Along the NE–SW linear structures, a top-to-the-NE sense of

166     shear is revealed by sigmoidal feldspar porphyroclasts within the orthogneiss and foliated granite, either

167     in the field or thin sections (Figure 7C–F).

168        At the south of the massif, foliations are well-developed in the Neoarchean to Paleoproterozoic

169     metamorphosed rocks, mainly dipping to the SW, SSE, or SE with moderate to low angles (Figure 6D).

170     The NE-SW linear structures, mostly at 65°/10°, are indicated by semi-penetrative mineral and

171     stretching lineations and the axes of isoclinal folds (Figures 6D, 8A and 8B). The mineral and stretching

172     lineation is defined by preferred orientation of biotite, K-feldspars and quartz aggregates (Figure 8A).

173     Along this NE–SW-trending lineation, a top-to-the-SW sense of shear is documented by asymmetric

174     lensed feldspar in the micaschist (Figure 8C), sigmoidal feldspar porphyroclasts in the mylonites

175     (Figure 8D), and other sigmoidal features as observed under the microscope (feldspar porphyroclasts:

176     Figure 8E, and mica fishes: Figure 8F).

177        Along the western boundary of the massif, decameter- to hectometer-thick ductile shear zone is

178     displaced by brittle sinistral Zhuwu fault, sealed by Early Cretaceous non-foliated Haiyang pluton to its

179  south, and covered by late stage of Early Cretaceous clastic rocks to its north (Figure 2). Brittle normal

180  faults overprinting the ductile shear zone represent the eastern boundary of the half-graben basin filled

181  with Early Cretaceous volcanic and clastic rocks (Figure 3). Mylonites in the Q pluton and its country

182  rocks exhibit a pervasive foliation parallel to the western margin of the massif approximately. The

183  mylonitic foliation gently dips to the NW, WNW, or SW at moderate to low angles (5°–40°), and

184  changes to SE or NE dips away from the western margin (Figures 2 and 6E). Whatever the dip direction

185  of the foliation, a conspicuous mineral and stretching lineation with a dominant WNW–ESE trend and

186  low plunges (0°–20°) is observed (Figure 6E). The lineation is marked by the preferred orientation of

187  feldspar and quartz aggregates (Figure 9A). At different scales, a top-to-the-WNW sense of shear is

188  indicated by asymmetric boudins, sigmoidal feldspar porphyroclasts and S-C fabrics (Figure 9B–F).

189      3.3 Microstructural study in the QKYS massif

190      3.3.1 Microstructural observation

191      In order to distinguish between solid-state and magmatic microstructures, the microstructural

192  observation is applied by many researchers and proved to be effective (Bouchez *et al*., 1990; Miller &

193  Paterson, 1994; do Nascimento *et al*., 2004; Xue *et al*., 2017, among others). The samples were cut

194  parallel to magnetic/mesoscopic lineation and perpendicular to magnetic/mesoscopic foliation to make

195  XZ thin sections. According to the criteria suggested by Bouchez *et al*. (1990, 1992), Paterson *et al*.

196  (1998), and Vernon (2000), four types of microstructures are discriminated, including (1) magmatic, (2)

197  sub-magmatic, (3) high-temperature solid-state and (4) low-temperature solid-state microstructures.

198  Typical photos of these microstructures are shown in Figure 10, and their spatial distribution shown in

199  Figure 11.

200      At the northeast of Q, and at the center of K, S and Y plutons, the granites display anhedral,

201  medium- to coarse-grained quartz free of deformation (Figures 10A and 11). Despite slight undulose

202    extinction in the quartz, the feldspars keep straight twin boundaries and euhedral biotite is no kinks or

203    bent boundaries. These features are typical of magmatic microstructure.

204    In the northern margin of K pluton, sub-magmatic microstructural features can be observed

205    (Figure 11). Under the microscope, microfractures in plagioclase or K-feldspar are filled by quartz,

206    which is considered as syn-magmatic deformation at the grain-scale in the presence of a residual melt

207    (Figure 10B). Meanwhile, most granites of the northern margin of K are characterized by recrystallized

208    quartz ribbons and K-feldspar core-mantle structure (Figure 10C and D), indicating high-temperature

209    solid-state microstructure.

210    The foliated to mylonitic gneiss in the northern and southern margins of the massif, and the

211    mylonitic granite with its country rocks in its western margin show low-temperature solid-state

212    microstructure (Figure 11). Plastic deformation in quartz is present in these foliated to mylonitic rocks,

213    marked by undulose extinctions, replacement of primary coarse-grained quartz by smaller and

214    elongated new grains (Figures 7F, 10E and F). Subrounded feldspars behave as rotated porphyroclasts

215    with trans-granular fractures (Figure 10E and F).

216    3.3.2 Quartz c-axes fabrics

217    Along the northern, southern, and western margins of the massif, quartz c-axis of the foliated

218    to mylonitic rocks are measured under the microscope by a universal-stage method to estimate

219    deformation temperatures. In the northern margin of the massif, three samples of foliated granite (KY05,

220    KY09 and KY57) and one sample of mylonitic orthogneiss (17JD35) were selected for the analysis of

221    Lattice Preferred Orientation (LPO) of quartz c-axes. Samples KY09 and KY57 are characterized by

222    point maxima around the mineral and stretching lineation (X-axis) and an elongated concentration at the

223    Y-axis (Figure 11), pointing to a combination of prism <c> and prism <a> slip of quartz under medium-

224    to high-temperature condition (500–600 °C; Stipp *et al.*, 2002). The sub-maxima surrounding the Z-axis

225    (Figure 11) can be explained by the simultaneous presence of basal <a> in addition to prism <c> and

226    prism <a> slip. The quartz fabric of KY05 is less clear, with a Z-maximum, a Y-maximum and a

227    subordinate cluster at X-axis, suggesting a combination of basal <a>, prism <a> and a subordinate

228    high-temperature prism <c> slip. Sample 17JD35 is dominated by point maxima around the Z axis,

229    indicating the presence of low-temperature (300–400 °C) basal <a> slip system. In conclusion, a

230    medium- to high-temperature condition for the foliated granite and a low-temperature condition for its

231    country rock, likely with a top-to-the-NE sense of shear, can be derived from these c-axis

232    measurements.

233        Measurements of quartz c-axes helped to estimate the temperature condition of the

234    top-to-the-SW shearing in the south of the massif. Three samples of mylonitic gneiss (18JD13, 18JD18

235    and 18JD28) and one mica schist (18JD29) were chosen. They exhibit asymmetric point maxima

236    located close to Z, the foliation pole, pointing to the basal <a> slip as the dominant system. In addition,

237    samples of 18JD28 and 18JD29 contain sub-maxima in-between Z and Y or close to Y, calling to the

238    activity of rhomb <a> slip (Figure 11). According to the natural and experimental data reviewed in

239    Passchier & Trouw (2005), a low-temperature condition (~300–400 °C) is responsible for this LPO

240    pattern of quartz c-axis. Meanwhile, the asymmetrical maxima around Z indicates a top-to-the-SW

241    shearing (Figure 11).

242        Five mylonite samples (QS27, QS30, QS37, QS43 and 18JD125) were chosen along the western

243    margin of the QKYS massif (Figure 11). Sample QS27, QS30, QS43 and 18JD125 display the

244    asymmetrical point maxima close to the periphery of the great circle and around the Z, implying basal

245    <a> slip (*e.g.,* Bouchez, 1977). Several sub-maxima in-between Z and Y are also presented in these four

246    samples, corresponding to the activity of rhomb <a> slip, attributed to low to medium temperature

247    condition (*e.g.,* Schmid & Casey, 1986, among others). Sample QS37 shows two asymmetrical c-axis

248    concentrations around Y, which is attributed to the rhomb <a> slip. We therefore estimate a low to

249    medium temperature around 350–450 °C for this deformation. Fabric asymmetry reveals a

250    top-to-the-WNW sense of shear, conformably to field and microscopic observation.

251    **4 Anisotropy of magnetic susceptibility (AMS) study**

252            AMS, as applied in many studies relative to granitic massifs, offers an effective way to refine

253    their structural elements, particularly among plutons that appear to be isotropic (*e.g.,* Bouchez, 1997;

254    Archanjo *et al*., 2002; Lehmann *et al*., 2013; Žák *et al*., 2015; Wei *et al*., 2014a, among others).

255            4.1 Sampling and measurement

256    A total of 111 sampling sites (47 from K pluton, 34 form Q pluton, 18 from S pluton and 12 from Y

257    pluton) were chosen for this study. Except for the southern part of K, where outcrops are limited,

258    granites were evenly sampled with 5 to 8 specimens for each site. They were drilled by a portable

259    gasoline drill, and oriented by a magnetic compass and a solar compass when possible. They were cut

260    into standard specimens with 2.2 cm in length and 2.5 cm in diameter. The AMS measurements were

261    performed using an AGICO Kappabridge magnetic susceptometer (MFK1) that works at a low

262    magnetic field in the Institute of Geology and Geophysics, Chinese Academy of Sciences, Beijing,

263    China. The AMS ellipsoid of a given specimen is characterized by three orthogonal principal axes (in

264    orientation and magnitude). For each site that includes a group of specimens, the AMS data were

265    processed using Anisoft 4.2 software to acquire site-average directions and magnitudes of three

266    principal axes, $K_1 \geq K_2 \geq K_3$ (Jelinek, 1978). The mean magnetic susceptibility ($K_m$) is equal to their

267    average value ($K_m = (K_1+K_2+K_3)/3$). Two magnetic fabric parameters $P_j$ and $T$ represent the degree of

268    anisotropy and the shape of the AMS ellipsoid, respectively. These parameters are defined as following:

269    $P_j=\{2[(\ln K_1-\ln K_m)^2+(\ln K_2-\ln K_m)^2+(\ln K_3-\ln K_m)^2]\}^{1/2}$ and $T=(2\ln K_2-\ln K_1-\ln K_3)/(\ln K_1-\ln K_3)$ (Jelinek,

270    1981).

271            Generally, $K_1$ and $K_3$ represent the magnetic lineation and the pole to the magnetic foliation,

272    respectively. To define the magnetic carriers, principally ferromagnetic or paramagnetic, and the

273    magnetic grain size of the magnetic carriers, principally pseudo-single domain or multidomain in

274    granites, three complementary measurements are necessary: (1) thermomagnetic curves, (2) isothermal

275    remanent magnetization and (3) hysteresis loops. These measurements were performed at the Institute

276    of Geology and Geophysics, Chinese Academy of Sciences, Beijing, China. Thermomagnetic curves

277    were obtained using a heating apparatus attached to the MFK1 susceptometer. Both isothermal

278    remanent magnetization and hysteresis loop measurements were obtained by using a Micro 3900

279    Vibrating Sample Magnetometer.

280          4.2 Magnetic mineralogy

281          The mean magnetic susceptibility ($K_m$) of measured sites are presented in Table 1, and the

282    frequency histograms are given in Figure 12. Overall, $K_m$ of S and Y plutons are mostly up to $10^{-2}$ SI in

283    susceptibility, implying that ferromagnetic minerals are the main magnetic susceptibility carriers ($K_m >$

284    $5 \times 10^{-3}$ SI, Hrouda & Kahan, 1991; Bouchez, 1997). The K and Q plutons have $K_m$ ranging from

285    $0.09 \times 10^{-3}$ SI to $57 \times 10^{-3}$ SI and $0.036 \times 10^{-3}$ SI to $16 \times 10^{-3}$ SI, respectively. In these two plutons, both

286    paramagnetic and ferromagnetic minerals are present; the paramagnetic minerals (iron-bearing silicates:

287    biotite and amphibole) become prevailing with a decrease of $K_m$.

288          All thermomagnetic experiments (Figure 13A, B and C) display a susceptibility drop at the

289    Curie temperature (~ 580 °C), revealing that iron-rich magnetite is the main susceptibility carrier. The

290    low-susceptibility specimens KY29 and QS22 exhibit hyperbolic thermomagnetic curves in their initial

291    parts, up to temperatures about 150°C or 250°C, reflecting a significant contribution (> 50%) of

292    paramagnetic minerals (*e.g.,* Trindade *et al*., 1999). The fact that the cooling curve has a higher

293    magnetic susceptibility than that of the heating curve (for example, KY29 in Figure 13A) indicates that

294    the original magnetic phase has been (partly) transformed into magnetite during heating. At an applied

295    magnetic field less than 200 mT, the isothermal remanent magnetization acquisition diagrams (Figure

296  13D, E and F) display a positive correlation between the induced magnetization and the applied field. At

297  a higher applied field up to 200 mT, the induced magnetization becomes constant, indicating that our

298  magnetite grains are weakly coercive. The ratios of $M_r/M_s$ and $H_{cr}/H_c$, acquired from the experiments of

299  isothermal remanent magnetization and hysteresis loops, indicate that the magnetic grain-size falls into

300  the pseudo-single domain (Dunlop, 2002; Figure 14). In fact, these characteristics of magnetic minerals

301  are common in the granites (*e.g.,* Trindade *et al.*, 1999; do Nascimento *et al.*, 2004, among others).

302      4.3 AMS fabric parameters and orientation

303      In our case, more than 95% of the measured samples of S and Y plutons have low $P_j$, less than

304  1.2. In K pluton, 70% of the $P_j$ values are less than 1.2 and remaining 30% are mainly distributed along

305  the pluton margin and contact zone with the S pluton (Figure 15A). In Q pluton, 29% of the $P_j$ values

306  exceed 1.2 and are present at its western part where low-temperature solid-state microstructures

307  dominate (Figures 11 and 15A). Majority of susceptibility ellipsoids are oblate, materialized by positive

308  *T* values: 69% in K pluton; 71% in Q pluton; 92% in S pluton, and 99% in Y pluton (Figure 15B and

309  Table 1), suggesting that planar fabrics are better defined than linear ones. The AMS ellipsoid becomes

310  more oblate along the northern margin of K pluton, western margin of Q pluton, and at the center part of

311  the Y pluton (Figure 15B). There is no positive or negative correlation between $P_j$ and $K_m$, or between *T*

312  and $K_m$ (Figure 15C and D), implying both the variations of $P_j$ and *T* are independent with $K_m$ values.

313  Also, there are no obvious correlativity between $P_j$ and *T* in most parts of these plutons (Figure 15F, G,

314  H and K). However, a rough positive relationship between $P_j$ and *T* is shown in the region I of K pluton,

315  region II of Q pluton, and in S pluton, implying that the AMS ellipsoids become more anisotropic and

316  more oblate at the same time (Figure 15E, I and J).

317      The tensorial mean orientation of each axis and confidence ellipses are shown on the lower

318  hemisphere equal-area projection (Figure 16). The orientations are considered as well-defined if their

319  confidence level ($\alpha_{95max}+\alpha_{95min}$) is less than 40° (Table 1). The magnetic foliations (planes normal to $K_3$)

320  and the lineations ($K_1$) are presented in map view of Figure 17, along with the corresponding orientation

321  diagrams giving sectorial summaries. The magnetic foliations of K pluton mainly exhibit concentric

322  patterns, and thereby we grouped them into three regions. In the region I, the granite samples show

323  mainly NE- or NNW- dipping magnetic foliations with small to moderate angles and magnetic

324  lineations in a NNE–SSW trend. They have neutral to oblate AMS ellipsoids and variable values of $P_j$

325  ranging from 1.038–1.433 (Figure 15E). In the center of K pluton (region II), the poles of magnetic

326  foliations define a broad, NNE–SSW striking girdle in the equal-area plot, and scattered magnetic

327  lineations with gentle plunges are shown. The AMS ellipsoids are dominated by oblateness, and the

328  values of $P_j$ are less than 1.2 (Figure 15F). The samples of region III are marked by inward dipping

329  magnetic foliations with moderate to high angles. In the equal-area plot, the magnetic lineations form a

330  cluster oriented at ENE–WSW and nearly normal to the broad girdle defined by the poles of magnetic

331  foliations. They also show prolate to neutral AMS ellipsoids and variable degrees of anisotropy (Figure

332  15G). In map view, the magnetic foliations of regions II and III form the "onion-skin" patterns with the

333  margin-parallel magnetic lineations (Figure 17).

334      In Q pluton, two distinct AMS fabric patterns are present (Figure 17). In region I, the magnetic

335  foliations mainly strike along NW–SE with varying angles (20°–80°) and contain scattered magnetic

336  lineations. Their AMS ellipsoids vary from oblateness to prolateness, with $P_j$ values ranging from

337  1.038–1.496 (Figure 15H). In region II, the magnetic foliations are mainly sub-horizontal, foliation

338  poles clustering at the center of the equal-area plot. The magnetic lineations display well-defined NW–

339  SE trends and small plunges. Their AMS ellipsoids are mainly oblate, with $P_j$ values ranging from 1.039

340  to 1.354 (Figure 15I).

341      In S pluton, the magnetic foliations have gentle outward dips, and the magnetic lineations

342  consistently plunge to the NW or SE with small angles. The AMS ellipsoids display neutral to oblate

343     shapes with weak anisotropy degrees, $P_j$ ranging from 1.028 to 1.295 (Figure 15J). Concerning Y

344     pluton, the magnetic foliations show the "onion-skin" pattern with nearly margin-parallel magnetic

345     lineations. Hence, the poles of magnetic foliations form a well-defined girdle through the center of the

346     equal-area projection, and the magnetic lineations have variable orientations with predominant outward

347     plunges. The AMS ellipsoids are much more oblate than the other plutons, most $T$ values being larger

348     than 0.5 (Figure 15B and K). Their anisotropy degree is weak with $P_j$ values mostly less than 1.2 (Figure

349     15K).

350     **5 Gravity Survey**

351     Gravity survey applied to numerous studies offer a probable way to reveal the geological

352     features at depth (*e.g.,* Guineberteau *et al*., 1987; Vigneresse, 1990; Vigneresse & Bouchez, 1997;

353     Gébelin *et al*., 2006; Turrillot *et al*., 2011, among others). In our study, the gravity map interpretation

354     and gravity modeling were carried out to characterize the unexposed parts shape of the QKYS massif.

355     5.1 Gravity map processing and interpretation

356     In order to extract the long wavelengths of the Bouguer anomaly, a low-pass Butterworth filter

357     with a cutoff wavelength of 150 km was applied on Bouguer anomaly map of Jiaodong Peninsula. The

358     residual gravity anomaly map, obtained through subtraction of the long wavelengths Bouguer anomaly

359     from the original anomaly map, mainly reflects the density heterogeneities in the upper crust of the

360     Jiaodong Peninsula (Figure 18).

361     In the residual gravity anomaly map, the iso-gravity trends are nearly parallel to the outcropping

362     plutons' borders at the scale of the Jiaodong Peninsula, and most of the plutons are represented by

363     negative gravity anomalies (Figure 18). In the QKYS massif itself, no substantial contrast appears

364     between the plutons and their country rocks, implying that (1) both the plutons and their country rocks

365     have similar densities; (2) low-density rocks are dominant in addition to plutons; and (3) some plutons

366   may extend off their outcropping boundaries at depth. A closer examination shows that the residual

367   Bouguer anomaly of the K pluton is elliptical in-shape with a N–S long axis. Its overall decreasing

368   gravity gradient toward the west and south indicates that K pluton becomes thinner and narrower in

369   these directions. Three clearly defined first-order negative anomalies are present in the center of K

370   pluton, in the south of S pluton and close to the contact zone between Q and Y plutons, implying that the

371   deep roots are present in these sectors.

372        5.2 Constraints for 2D gravity modeling

373        To obtain a realistic geometry of QKYS massif, we measured the density values of plutons and

374   their country rocks by the double-weighing method. We obtained: (1) 2600 kg/m$^3$ and 2580 kg/m$^3$ for

375   Late Jurassic K and Q biotite monzonitic granite and Early Cretaceous S and Y porphyritic granite,

376   respectively; (2) 2670 kg/m$^3$ for Early Cretaceous diorite; (3) 2790 kg/m$^3$ for Paleoproterozoic

377   meta-sedimentary rocks including the paragneiss, schist, amphibolite and marble; (4) 2630 kg/m$^3$ for the

378   gneissic migmatite in the north of the massif, and 2720 kg/m$^3$ for the heavier gneiss to the south of the

379   massif, due to the addition of the meta-mafic lenses; and (5) 2550 kg/m$^3$ for Early Cretaceous volcanic

380   and clastic rocks.

381        Topographic corrections of the residual anomaly map were performed based on the International

382   Gravimetric Bureau database (Bonvalot *et al*., 2012). Based on our field structural analysis, geological

383   map, residual gravity anomaly map and density measurements, we have built a gravity model in the

384   "Oasis montaj" platform of Geosoft (www.geosoft.com). The density of undifferentiated upper crust

385   was chosen as 2800 kg/m$^3$, according to the Crust 1.0 model of Laske *et al.* (2013). All layers were set to

386   be nearly flat and extend at infinity to avoid edge effects. Finally, each unit in the profiles was

387   considered to have a constant density, appropriate to obtain the best match between measured and

388   calculated gravity values.

389     5.3 Gravity profiles

390     Five NE–SW-trending and six NW–SE-trending modeled gravity profiles (Figure 19)

391   crosscutting all litho-tectonic units in the study area, allow us to characterize the shape of QKYS massif

392   at depth. According to these gravity profiles, several features can be outlined. The country rocks

393   (gneissic migmatite and meta-sedimentary rocks) of the plutons have a thickness around 5 km. The K

394   and Q plutons are rather batholithic with considerable thickness variations. In the NE–SW profiles,

395   these two plutons count to three roots deeper than ~6 km (Figure 19A–E), and in-between these roots

396   their thickness is 2–3 km. In the NW–SE profiles (Figure 19F–K), the Q pluton has a constant

397   thickness of 2 to 4 km with no obvious deeper root. The K pluton also displays a constant thickness of

398   2–4 km with no obvious root in profiles F, J and K, and a flat bottom (~5 km) thinning to the northwest

399   and southeast in profiles G, H, and I. When aligning these roots in the gravity map (Figure 18), we

400   argue that the K and Q plutons are made of several NW–SE-trending deeper roots. Concerning the S

401   and Y plutons, both the NE–SW and the NW–SE profiles reveal that they have an inverted drop shape

402   with a single ~5 km deep root (Figure 19). Profiles H to K show that the top of Q pluton is covered by 1

403   to 2 km-thick Early Cretaceous volcanic and clastic rocks. The contact between Q pluton and Early

404   Cretaceous volcanic and clastic rock is arch-shaped and becomes steep at depth (Figure 19I, J and K).

405   **6 Discussion**

406     6.1 Origins of the magnetic fabrics

407     Both the paramagnetic and ferromagnetic minerals (*i.e.,* biotite, amphibole, and magnetite) act

408   as the main AMS carriers, the magnetic fabrics being due to their shape preferred orientation (SPO).

409   The mesoscopic foliation and lineation also result from SPO of the paramagnetic minerals (Figures 2

410   and 17). In region I of Q pluton and regions I, II and III of K pluton, the granites show concentric

411   magnetic foliations. Predominant NNE–SSW-trending magnetic lineations are present in region I of K

412    pluton, which are parallel to the linear structures in the northern margin of the K pluton. Away from

413    the northern margin of the K pluton, the magnetic lineations become more scattered (region I of Q

414    pluton and region II of K pluton) or parallel to the magnetic foliation strikes (region III of K pluton).

415    These granite samples are characterized by magmatic, sub-magmatic or high-temperature solid-state

416    microstructures (Figure 11). Combined with the geometric relations of plutons and their country rocks

417    (*c.f.* section 3), we suggest their magnetic fabrics were acquired during the late stages of magma

418    crystallization, recording increments of the regional tectonic strain (*e.g.,* Žák *et al*., 2015; Paterson *et*

419    *al*., 2019). In region II of Q pluton, the granites have flat magnetic foliations and NW–SE magnetic

420    lineations (Figure 17). They also have low-temperature solid-state microstructures (Figure 11) that

421    correlate well with the higher $P_j$ and $T$ values (Figure 15A and B). Their magnetic fabrics correspond

422    to the mylonitic foliations and lineations observed in the western margin of Q pluton (*e.g.,* Lin *et al*.,

423    2013b).

424         The S and Y plutons show typical features of isotropic granitoids with magmatic

425    microstructure, low $P_j$, and no post-solidus recrystallization. Together with the extremely fast cooling

426    rate they display (Figure 4D), we argue that their magnetic fabrics are devoid of the influence of

427    regional tectonics (*e.g.*, Paterson et al., 1998; Yoshinobu et al., 1998). In other words, their magnetic

428    fabrics were acquired during magma crystallization without the contribution of syn- or

429    post-emplacement tectonics.

430         6.2 Polyphase deformation and multiple pluton emplacement

431         Based on field observation and laboratory analyses, a polyphase deformation is recognized in

432    the QKYS massif. The polyphase deformation corresponds to several tectonic events in East China.

433         6.2.1 $D_1$ deformation and its tectonic significance

434         Along the northern margin of the massif, mesoscopic foliations of the country rocks

435   (orthogneiss) and the granitic rocks are parallel in orientation, and both contain the NE–SW linear

436   structures with top-to-the-NE kinematics (Figure 20). This event is characterized by high-temperature

437   deformation in the granitic rock and low-temperature deformation conditions in the orthogneiss

438   (Figures 7, 10 and 11), a complete parallelism appearing between the magnetic fabrics and the

439   structural elements of these high- to low-temperature solid-state fabrics (Figure 20). Decrease of $P_j$

440   and $T$ values is interpreted as the strain weakening from the margin to the core of the K pluton (Figure

441   15A and B). The age of first deformation event (*i.e.,* $D_1$ event) is therefore similar to the crystallization

442   age of the syn-kinematic K pluton (*i.e.,* 153 Ma, Figure 4B). The NW–SE trending roots of K and Q

443   plutons are considered as the feeder zones (Figures 18 and 19; *e.g.*, Améglio *et al*., 1997). Location of

444   these feeder zones at the centers of the magnetic foliations concentric patterns naturally implies that the

445   magma upwelled above them (Figures 17, 19 and 20; *e.g.,* Ji *et al*., 2018b).

446        From the view of these structures, a NE–SW extensional tectonics was likely responsible for

447   the $D_1$ event which is characterized by the emplacement of a syn-kinematic pluton (K pluton) and a

448   normal sense of shear. In such a scenario (Figure 21A), the Late Jurassic magma ascent through several

449   feeder zones almost perpendicular to the NE–SW extensional direction (*e.g.,* Vigneresse, 1995), and

450   then expanded laterally along the extensional direction to form a single pluton at the middle crustal level

451   (ca. 15 km). By the end of magma crystallization, due to the progressing extension, a ductile normal

452   shear zone developed on the northern margin of the massif (Figure 21A).

453        6.2.2 Latest Jurassic to Earliest Cretaceous contractional $D_2$ event

454        In the south of the QKYS massif, the ductile shear zone displays a gentle SW dipping foliation,

455   a NE–SW linear structure, and a top-to-the-SW kinematics under low temperature condition (Figures 11

456   and 20). Because this tectonic event was not recognized before, rare geochronological works were

457   documented to constrain its age. Undeformed Early Cretaceous porphyritic granite intruded the

458   mylonitic rocks (Figures 20 and 21), so its crystallization age (118 Ma, Charles *et al.*, 2011b) give a

459    minimum for this event. The amphibole and biotite $^{40}Ar/^{39}Ar$ dating for the gneiss and amphibolite from

460    the lower part of the shear zone yield distinct ages of 219–195 Ma and135–133 Ma, respectively (Figure

461    4C, Chen *et al*., 1992; Wu, 2014; Liu *et al*., 2017a). Considering its low deformation temperature, a little

462    higher than the biotite closure temperature (*ca*. 280–320 °C), and much lower than that of amphibolite

463    (*ca*. 480–550 °C), we interpreted that its timing approaches or slightly earlier than 135 Ma ($D_2$ event).

464          From the viewpoint of the geometry, the SW-dipping foliations with top-to-the-SW shearing

465    could be interpreted as a SW-directed extensional structure. In this case, the north and south shear zones

466    with normal senses of shear could announce the exhumation of a magmatic dome in a NE–SW direction,

467    similarly to the extensional domes in South China (Faure *et al*., 1998; Lin *et al*., 2001) and Montagne

468    Noire in SE France Central Massif (Echtler & Malavieille, 1990). However, two lines of evidence

469    exclude the model of symmetric extension for the QKYS massif. Firstly, no high-temperature plastic

470    flow similar with the $D_1$ shear zone is observed along the southern or southwestern margin of the K

471    pluton. Secondly, to the south of the K pluton, the foliations of the country rocks are oblique with

472    respect to magnetic foliations of pluton, as well as to the granite/orthogneiss contact (Figure 20). From

473    the view of regional geology, similar top-to-the-SW ductile deformations with the ages of 143–138 Ma

474    were recognized in the northern part of NCC and central part of SCB, which are interpreted as NE–SW

475    contractional structures (Davis *et al*., 2001; Lin *et al*., 2013a; Zhu *et al*., 2015; Ji *et al*., 2018a).

476    Considering the Early Cretaceous exhumation and the Late Cretaceous to Cenozoic differential

477    uplifting of the massif, it is reasonable to infer that the dips of the $D_2$ shear zone foliations may vary

478    from NE- to SW-directed (Figure 21B–D). Either its kinematics or timing can be comparable with

479    SW-directed thrusting documented in East China (Davis *et al*., 2001; Lin *et al*., 2013a; Zhu *et al*., 2015;

480    Ji *et al*., 2018a), so we interpret this deformation as an independent event related to the latest Jurassic to

481    earliest Cretaceous NE–SW contractional tectonics.

482        6.2.3 Early Cretaceous extensional D$_3$ event

483        Along the western margin of the massif, the flat-lying ductile shear zone with a

484    top-to-the-WNW kinematics separates the massif from Early Cretaceous unmetamorphosed volcanic

485    and clastic rocks (Figure 20). The flat magnetic foliations with NW–SE magnetic lineations in region

486    II of the Q pluton is also remarkable of this event (Figure 17). The structural fabrics of the orthogneiss

487    located between Q and K pluton, at odd with the magnetic fabrics of the plutons, suggest a pre-Late

488    Mesozoic deformation (*e.g.*, Faure *et al.*, 2001, 2003). Previous studies considered this shear zone as a

489    detachment fault, therefore pointing to an extensional structure (Shen *et al*., 1998; Xia *et al*., 2016).

490    Meanwhile, the undulated shape of the detachment fault likely results from an extension-parallel

491    corrugation (e.g., Richard et al., 1990). The gravity modeling shows that the flat-lying detachment

492    fault becomes steeper at depth (Figure 19). This geometry likely corresponds to a rolling-hinge structure

493    that was originated from an initial steep fault, favoring the exhumation of the QKYS massif (*e.g.*, Axen

494    *et al*., 1995). Rolled around the hinge of the detachment fault, the footwall rocks were progressively

495    exhumed to reach a shallower crustal level (*e.g.,* Ratschbacher *et al*., 2000; Yin, 2004). Hence, the Q

496    pluton located immediately below the detachment has a younger cooling age than the K pluton which

497    is far from the fault (Figure 4C). When the detachment fault reached the shallower crust, the

498    west-dipping brittle normal fault overprinted the ductile shear zone, hence controlled the development

499    of Early Cretaceous half-graben basin (Figure 21C; e.g., Xia *et al.*, 2016).

500        The supra-detachment basin is filled by Early Cretaceous volcanic and clastic rocks (Wang et

501    al., 2016), suggesting the same age for the detachment fault. Muscovite and biotite yielded 128–126

502    Ma and 124–120 Ma $^{40}$Ar/$^{39}$Ar ages for the mylonitic Q granite (Figure 4C; Li *et al*., 2006; Zhang *et al*.,

503    2007; Wu, 2014). To the east, $^{40}$Ar/$^{39}$Ar ages on biotite samples from K pluton give 130–126 Ma,

504    representing the cooling ages of K pluton. These geochronological data indicate that the 130–120 Ma

505    approaches the true age of the detachment fault, in agreement with a fast cooling rate of the massif

506    during this period (Figure 4D). Hence, this event took place after D$_2$; it is named D$_3$.

507        6.2.4 Emplacement of Early Cretaceous plutons

508        The segregation and ascent of magma is usually commenced by the way of dyking or diapir (*e.g.*,

509    Clemens & Mawer, 1992; Kratinová *et al*., 2006). Thermomechanical models indicate that magma

510    ascent as a diapir is prone to stop at depth, *i.e.*, at the middle to lower crust level (Cao *et al*., 2016). Dou

511    *et al*. (2018) constrained that the S and Y plutons were emplaced at a pressure of 1.8–2.1 kbar by using

512    the experimental Qz-Ab-Or phase diagram, corresponding to depths of 5.4–6.3 km, so the diapir model

513    is inappropriate. Clemens and Mawer (1992) suggested a model of self-propagating dyking in which the

514    magmas should produce the tensile fracturing, and providing the space for magma ascent, while the

515    re-activation of pre-existing weak zones are also expected to facilitate the initiation of dyking (*e.g*., Baer,

516    1991). Early Cretaceous S and Y plutons are inverted drop shaped with a single feeder zone as revealed

517    by the gravity profiles (Figure 19), suggesting that they were emplaced through a single sub-vertical

518    weakness zone (*e.g.,* Guineberteau *et al*., 1987; Améglio *et al*., 1997). The magnetotelluric profile of

519    Zhang *et al*. (2018) also supports a highly fractured upper crust in the Jiaodong Peninsula. Hence, the

520    reactivation of pre-existing fractures in the upper crust was probably a preferential mechanism for the

521    emplacement of these plutons (Figure 21D; *e.g.,* Liu *et al*., 2018). At the end of magma ascent, and in

522    absence of regional tectonics, magma convection led to the "onion-skin" magnetic foliations and

523    margin-parallel magnetic lineations of the Y pluton (Figure 17). The gently dipping magnetic foliations

524    recorded in S pluton likely represent the sub-horizontal roof at the top of the pluton (Figure 17).

525        Two Early Cretaceous plutons, namely Haiyang (118 Ma) and Weideshan pluton (108 Ma) have

526    been documented in the Jiaodong Peninsula (Figure 1). These porphyritic granodiorites share common

527    features with the S and Y plutons (Charles *et al*., 2011b), namely: (1) typical isotropic textures without

528    obvious solid-state fabrics; (2) sub-horizontal and outward dipping magnetic foliations with scattered

529    magnetic lineations; and (3) a fast cooling rate revealed by zircon U-Pb and biotite $^{40}$Ar/$^{39}$Ar ages.

530 Accordingly, isotropic pluton emplacement, devoid of the influence of regional tectonics and whose

531 emplacement was controlled by pre-existing structures, have prevailed during the 118–108 Ma time

532 interval.

533        6.3 Tectonic significance of the polyphase deformation in the QKYS massif

534        Polyphase deformation and multiple magmatic events recorded in the QKYS massif helped us to

535 understand the Late Mesozoic tectonic evolution of East China (Figure 22). The Late Jurassic volcanic

536 rocks and simultaneous felsic intrusions are widely distributed in the Yanshan-Yinshan belt, Liaodong

537 Peninsula and Jiaodong Peninsula, forming a magmatic flare-up between 170 and 150 Ma in East

538 China (Wu *et al.*, 2019). Coeval with this intensive magmatism, extensional basins are well-developed

539 in East China, suggesting a Late Jurassic extensional tectonics (Meng, 2003; Cope et al., 2007; Faure

540 *et al.*, 2012; Dong *et al.*, 2015). In our case, the $D_1$ event with a top-to-the-NE kinematics,

541 accompanied by syn-kinematic magmatism (referred to $Mag_1$), also supports the view of a significant

542 episode of Late Jurassic extensional tectonics (Figure 22A).

543        In East China, long-term magmatism lasts from 170 to 110 Ma with a significant "magmatic gap"

544 between 150 and 135 Ma, inferring a $J_3$–$K_1$ contractional tectonics (Li, 2000; Wu *et al.*, 2019). The

545 regional unconformity and E–W fold and thrust structures also indicate a NE–SW contractional

546 tectonics during the latest Jurassic–earliest Cretaceous (Wong *et al.*, 1929, among others). A

547 representative southward thrusting named Gubeikou fault is dated at148–132 Ma in the Yanshan area

548 (Davis *et al.*, 2001). In the Lingyuan-Qinglong area, a regional SE-directed thrusting, previously

549 considered by Davis *et al*. (2009) as Late Triassic or pre-middle Jurassic, was recognized as a latest

550 Jurassic event by Hu *et al*. (2010). A $J_3$–$K_1$ SE-directed thrusting also has been documented in the

551 Liaodong Peninsula (Qiu *et al.*, 2018). Even though the fold and thrust structures have variable

552 directions, ductile deformation events developed in the Sihetang, Yiwulüshan, and Jiaodong Peninsula,

553    referred to as the $D_2$ event in this study, pointing to a top-to-the-SW kinematics (a summary in the

554    Figure 22B; Davis *et al.*, 2001; Lin *et al.*, 2013a; Zhu *et al.*, 2015).

555        Recognition of Early Cretaceous extensional $D_3$ event in the study area is consistent with

556    previous studies about MCC, magmatic domes, syn-kinematic plutons, and detachment faults in East

557    China (Figure 22C; Davis *et al.*, 2002, among others). These extensional structures share common

558    features, such as the conspicuous NW–SE linear structures with either top-to-the-NW or top-to-the-SE

559    kinematics, coupled supra-detachment basins (Lin & Wei, 2018). The dating of syn-kinematic minerals

560    constrains these structures to be 130–115 Ma in age, in agreement with the timing of the $D_3$ event of

561    QKYS massif (Wang *et al.*, 2012; Zhu *et al.*, 2015; Lin & Wei, 2018 and references therein). In this

562    period, several extensional basins, intensive magmatism, and gold mineralization likewise occurred in

563    East China, associated with the extensional tectonics (Ren *et al.*, 2002; Meng, 2003; Lin *et al.*, 2019).

564    After then, fractures development in the upper crust provided the channels for Early Cretaceous magma,

565    here referred to $Mag_2$ event.

566        6.4 Geodynamic Implications

567        Geodynamics of the Jurassic–Cretaceous tectonics of East China remains enigmatic. Several

568    models have been proposed, including (1) subduction of the Izanagi plate beneath Eastern Eurasian

569    continent (Xu & Wang 1983; Zhu *et al.*, 2011, 2012); (2) closure of the Mongol-Okhostk Ocean (Yin

570    & Nie, 1996; Davis *et al.*, 2001); (3) collision between the Lhasa and the Qiangtang terranes (Ma *et*

571    *al.*, 2017). Subduction of Izanagi Plate with the slab roll-back is responsible for the Late Mesozoic

572    extension in East China (Ren *et al.*, 2002; Zhu *et al.*, 2011, 2012). Induced by the Izanagi Plate

573    subduction, partial melting of lower crust took place at Late Jurassic, forming the intermediate to

574    felsic calc-alkalic magmatism in East China (*e.g.*, Li *et al.*, 2019). Recently, Wu *et al.* (2019)

575    proposed that the Izanagi Plate subduction angle changed from steep to flat, followed by slab roll-back

576  during Jurassic–Early Cretaceous times to interpret the episodic extensional and contractional

577  tectonics in East China. In our case, the Late Jurassic NE–SW extension ($D_1$) and the Early

578  Cretaceous NW–SE extension ($D_3$) also corresponds to the subduction direction variation deduced

579  from the model of Mattauer et al. (1997) (Figure 22). Final closure of the Mongol-Okhotsk ocean is

580  constrained at Late Jurassic–Early Cretaceous according to the paleomagnetic results (van der Voo *et*

581  *al.*, 2015). It is likely to interpret the $J_3$–$K_1$ contractional tectonics and "magma quiescence" in East

582  China, as previously proposed by Yin & Nie (1996) and Davis *et al.* (2001). However, the

583  non-significant reactivation of the Solonker-Xilamulun belt, located between the Mongol-Okhotsk and

584  NCC and considered as a weak zone due to the Late Paleozoic accretionary orogenic belt, is not well

585  explained (*e.g.*, Lin *et al.*, 2013a). Ratschbacher *et al.* (2000) proposed that the model of interaction

586  between Pacific back-arc extension and tectonic escape related to the collision between Qiangtang and

587  Lhasa is a possible mechanism to explain Early Cretaceous extension. However, recent SKS wave

588  splitting data seem to discard the eastward escape of the NCC (Zhao *et al.*, 2011).

589      The rapid change from the latest Jurassic to earliest Cretaceous crustal contraction($J_3$–$K_1$) to

590  Early Cretaceous crustal extension favors that a previous thickened has a significant effect on

591  subsequent intense crustal extension. From the view of regional tectonics, multi-plate convergence

592  around East China may account for its crustal thickening at latest Jurassic to earliest Cretaceous (*e.g.*,

593  Dong *et al.*, 2015). Numerical modeling also suggests that a thickened continental crust facilitates the

594  decoupling between the upper crust and the lower crust, leading to intensive extension (Gueydan *et al.*,

595  2008). Furthermore, the model of lithosphere foundering is speculated to be a significant mechanism

596  that resulted in the loss of the lithospheric root beneath East China, through which the continental crust

597  and lithospheric mantle are highly decoupled (Lin & Wang, 2006; Lin & Wei, 2018). Subsequent

598  asthenospheric upwelling led a high mantle heat flux able to weaken the middle-lower crust, favoring

599  the setting of the exhuming domes (Brun *et al.*, 2018). In a plate tectonic framework (Figure 22C), the

600 NW-directed subduction of the Izanagi Plate and its subsequent roll-back may enhanced the lithospheric

601 foundering at the origin of the vast extensional tectonics during the Early Cretaceous (*e.g.*, Lin & Wei,

602 2018; Chu *et al.*, 2019).

603 **7 Conclusions**

604     Three phases of deformation and two periods of magmatism recognized in a single area (QKYS

605 massif) allow us to understand Late Mesozoic episodic intracontinental extension and contraction of

606 East China. We have presented detailed structural analyses, magnetic fabrics and gravity modeling,

607 documenting an Late Mesozoic extension-contraction-extension history that QKYS massif experienced.

608 Our new data, together with published work, suggests that East China suffered Late Jurassic NE–SW

609 extension, latest Jurassic–earliest Cretaceous NE–SW contraction, then to Early Cretaceous NW–SE

610 extension. This periodicity likely links with the subduction of Izanagi Plate beneath Eurasian continent,

611 inferring a variation from oblique to orthogonal subduction during the Late Mesozoic.

1070    **Figure captions**

1071    **Figure 1.** Tectonic sketch of the northern part of Jiaodong Peninsula (*after* Faure *et al*., 2003a) with the

1072    location of the study area. Inserted diagram showing the tectonic position of East China with the

1073    multi-plate convergences surrounding it.

1074    **Figure 2.** Simplified geological map of the Queshan-Kunyushan-Yuangezhuang-Sanfoshan (QKYS)

1075    massif. Foliations and lineations are based on our field work; they show the domal architecture of the

1076    massif. Abbreviations are same as the Figure 1.

1077    **Figure 3.** Geological cross-sections across the QKYS massif (locations are shown in Figure 2). A:

1078    Cross-section drawn parallel to the direction of the SW–NE. B and C: WNW–ESE cross-sections

1079    parallel to the direction of the ductile deformation in the western margin.

1080    **Figure 4.** Available geochronological data of the QKYS massif. All the data are collected from

1081    previous studies (Legends and abbreviations are the same in Figure 2). A: Zircon U-Pb ages of the Late

1082    Mesozoic plutons. B: Density plot of zircon U-Pb ages from the Late Mesozoic plutons showing their

1083    peak ages. C: $^{40}Ar/^{39}Ar$ cooling ages of the massif. D: Cooling history of the massif to constrain the

1084    timing of polyphase deformation events.

1085    **Figure 5.** Field photographs of the Late Jurassic and Early Cretaceous plutons. A: Late Jurassic

1086    Kunyushan undeformed biotite monzogranite (KY20: 37.1109°N, 121.7139°E). B: Late Jurassic

1087    Kunyushan foliated biotite monzogranite (18JD59: 37.3275°N, 121.7749°E). C: Late Jurassic Queshan

1088    mylonitic granite (QS43: 37.1231°N, 121.3873°E). D: Early Cretaceous undeformed porphyritic biotite

1089    monzogranite with large K-feldspar phenocrysts (YG10: 37.2880°N, 121.4306°E).

1090    **Figure 6.** Field structures represented as equal-area lower hemisphere diagrams of the planar and linear

1091    structures related to the ductile deformation developed in the QKYS massif.

1092    **Figure 7**. Field and microscope photos of the deformed granite in the northern margin of the K pluton

1093    and gneissic country rocks, displaying a top-to-the-NE sense of shear. A: NE–SW mineral lineation

1094    marked in the foliated granite by biotite and quartz aggregates (19JD127: 37.3786°N, 121. 7445°E). B:

1095    Isoclinal fold with axis plunging to NE developed in the orthogneiss (17JD35: 37.3415°N, 121.7575°E).

1096    C: Sigma-type K-feldspar in the foliated granite (19JD127: 37.3786°N, 121. 7445°E). D: Asymmetric

1097    felsic boudin within the orthogneiss (17JD35:37.3415°N, 121.7575°E). E: Sigma-type plagioclase

1098    porphyroclast and "ribbon-like" quartz grains in the foliated granite (KY57: 37.2789°N, 121.8502°E). F:

1099    In the gneiss (17JD35: 37.3415°N, 121.7575°E), quartz and feldspars showing sigma-type features and

1100    low-temperature deformation. Symbols: Qz: quartz; Pl: plagioclase; Kfs: K-feldspar; Bi: biotite; Amp:

1101    amphibole.

1102    **Figure 8.** Field and microscope photos of the metamorphic rocks from the south of the QKYS massif,

1103    all showing a top-to-the-SW shearing. A: ENE–WSW-trending mineral and stretching lineation marked

1104    by mineral aggregates in a mylonite (18JD28: 36.8016°N, 121.5354°E). B: Isoclinal fold axes parallel

1105 to a N50° stretching lineation formed by muscovite and feldspar aggregates (18JD29: 36.7503°N,

1106 121.5576°E). C: Asymmetric felsic boudins within the mica schist (18JD29: 36.7503°N, 121.5576°E).

1107 D: Sigma-type feldspar porphyroclasts in the mylonite (18JD28: 36.8016°N, 121.5354°E). E:

1108 Microphotograph of the sigma-type feldspar porphyroclast in a felsic mylonite (18JD13: 36.8309°N,

1109 283 121.4490°E). F: Microphotograph of muscovite "fish" in a mica schist (18JD29: 36.7503°N,

1110 121.5576°E) showing the same asymmetry. Symbols: Qz: quartz; Pl: plagioclase; Mus: muscovite.

1111 **Figure 9.** Field, hand-sample, and microscope photos of the mylonitic Q granite and its country rocks,

1112 showing a top-to-the-WNW shearing. A: WNW–ESE lineation defined by biotite and feldspar

1113 aggregates in the granite (QS29: 37.1317°N, 121. 2507°E). B: Asymmetric and top-to-the-WNW

1114 sheared felsic lenses in the meta-sedimentary rock (QS37: 37.0279°N, 121.3374°E). C: Sigma-type

1115 feldspar porphyroclasts in the granite (QS28: 37.1598°N, 121. 2585°E). D: S-C fabric and sigma-type

1116 feldspar porphyroclasts in the granite (QS43: 37.1231°N, 121.3873°E). E: Thin section: sigma- and

1117 delta-type porphyroclasts in the granite (QS41: 37.0995°N, 121.3943°E). F: Thin section: asymmetric

1118 feldspar porphyroclast surrounded by fine-grained quartz grain in the granite (QS28: 37.1598°N, 121.

1119 331 2585°E). Symbols: Qz: quartz; Pl: plagioclase; Kfs: K-feldspar; Bi: biotite.

1120 **Figure 10.** Typical microphotographs showing the microstructures of the QKYS massif. A: Typical

1121 magmatic fabric with undeformed quartz, plagioclase, biotite, and K-feldspar (SF02: 36.9333°N,

1122 121.6890°E). B: Quartz-veinlet cross-cutting a plagioclase with undulatory extinction, showing that the

1123 deformation ended at relatively low temperature and rather high stress (KY09: 37.2360°N, 121.9220°E).

1124 C: Plagioclase phenocrysts surrounded by "ribbon-like" quartz grains with straight boundaries (KY57:

1125 37.2789°N, 121.8502°E). D: K-feldspar showing the core-mantle structure (KY57: 37.2789°N,

1126 121.8502°E; lower: plane-polarized light; upper: cross-polarized light). E: Low-grade mylonite,

1127 showing the broken K-feldspar with the foliated matrix of tiny recrystallized quartz (18JD13:

1128 36.8309°N, 121.4490°E). E: The quartz grains are recrystallized to form the new grains with irregular

1129    boundaries, showing the shape preferred orientation (QS40: 37.0989°N, 121.3904°E). Symbols: Qz:

1130    quartz; Pl: plagioclase; Kfs: K-feldspar; Bi: biotite.

1131    **Figure 11.** Kinematic map for the tectonic events in the QKYS massif and quartz LPO diagrams

1132    obtained by universal stage measurement (Captions are the same as in Figure 2). Arrows point to the

1133    sense of shear of the upper layer over the lower layer. Samples are foliated or mylonitic monzogranite

1134    (KY05, KY09, KY57, QS27, QS30, QS43, 18JD125), mylonitic gneiss (17JD35, 18JD13, 18JD18 and

1135    18JD28) and mica schist (QS37 and 18JD29). Equal-area lower hemisphere diagrams drawn in the XZ

1136    section of the bulk strain ellipsoid (*i.e.,* perpendicular to foliation and parallel to the mineral and

1137    stretching lineation). Contour intervals given as multiple of random distribution are shown for each

1138    sample.

1139    **Figure 12.** Frequency histograms of $K_m$ for all the AMS sites.

1140    **Figure 13.** Magnetic mineralogy investigation concerning granite plutons in the QKYS massif. A–C:

1141    Thermomagnetic curves. D–F: Acquisition of isothermal remanent magnetization.

1142    **Figure 14.** $M_{rs}/M_s$ versus $H_{cr}/H_c$ diagram defining the grain size of magnetite. $M_{rs}$: remanence of

1143    saturation magnetization after removing the applied field; $M_s$: saturation magnetization under applied

1144    field; $H_{cr}$: coercivity of remanence after removing the applied field; $H_c$: coercivity under applied field.

1145    SD: single domain; PSD: pseudo single domain; MD: multi-domain.

1146    **Figure 15.** AMS scalar parameters for the analyzed plutons. A: Distribution of $P_j$ within each pluton

1147    (Captions are the same as in Figure 2, and the offset of Zhuwu Fault is restored). B: Distribution of $T$

1148    within each pluton. C: $P_j$ versus $K_m$ diagram showing the absence of correlation between them. D: $T$

1149    versus $K_m$ diagram showing the absence of correlation between them. E–K: $T$ versus $P_j$ diagrams of each

1150    region of these four plutons. $T$: shape factor; $P_j$: anisotropy degree; $K_m$: mean bulk magnetic

1151    susceptibility in $10^{-3}$ SI.

1152    **Figure 16.** Lower hemisphere equal-area projections of AMS axes for each pluton, with confidence

1153  ellipses at 95%. A: Kunyushan pluton (K); B: Queshan pluton (Q); C: Yuangezhuang pluton (Y) and D:

1154  Sanfoshan pluton (S). Small symbols represent each individual specimen and large ones represent the

1155  tensorial mean out of 5–8 specimens.

1156  **Figure 17.** Magnetic fabric maps of the Late Mesozoic plutons in the QKYS massif, showing the

1157  magnetic foliations/lineations and corresponding orientation diagrams (of their poles) in each region.

1158  All orientation diagrams are lower hemisphere, equal-area projections.

1159  **Figure 18.** Residual Bouguer gravity map of the Jiaodong Peninsula obtained by subtraction of a 150

1160  km wavelength regional trend from the original Bouguer gravity map. The red rectangles represent

1161  possible feeder zones of Late Jurassic plutons, and they show a rough NW–SE-trending when aligning

1162  them.

1163  **Figure 19.** Forward gravity modeling across the QKYS massif revealing its geometry at depth. Along

1164  NE–SW profiles (A–E), and NW–SE profiles (F–K). The profiles are in Figure 18.

1165  **Figure 20.** Block diagram showing the bulk geometry, kinematics of the QKYS massif and illustrating

1166  the polyphase deformation ($D_1$, $D_2$ and $D_3$) and magmatism ($Mag_1$ and $Mag_2$).

1167  **Figure 21.** A possible tectonic scenario implied from the QKYS massif, pointing to episodic extension

1168  and compression tectonics. In these diagrams, we considered the emplacement depth of Late Mesozoic

1169  plutons (Dou et al., 2018) as the reference to describe the emplacement-exhumation process of the

1170  massif from deep to shallower crustal level. A (165–153 Ma): Emplacement of Late Jurassic plutons

1171  ($Mag_1$) at a NE–SW extensional setting, coeval with a high- to low-temperature top-to-the-NE shearing

1172  ($D_1$); B (153–135 Ma): NE–SW compressional deformation with low-temperature top-to-the-SW sense

1173  of shear ($D_2$); C (130–115 Ma): WNW–ESE regional extension tectonics corresponding to the

1174  low-temperature top-to-the-WNW shearing ($D_3$) and leading the QKYS massif exhumed; D (post-115

1175  Ma): Emplacement of Early Cretaceous plutons ($Mag_2$) via the opened fractures and subsequent

1176  erosion.

1177   **Figure 22.** East China surrounded by multi-plate convergences during Late Mesozoic (modified after Ji

1178   *et al*., 2018b and Lin & Wei, 2018). The subduction direction of the Izanagi Plate is based on Maruyama

1179   *et al*. (1997). Late Mesozoic extensional and compressional structures are marked to show their spatial

1180   and temporal distribution. NCC: North China Craton; SCB: South China Block; CAOB: Central Asian

1181   orogenic belt; YS–YS: Yinshan–Yanshan fold and thrust belt; JD: Jiaodong Peninsula; TLF: Tan–Lu

1182   fault; THS: Taihangshan; Gbk: Gubeikou fault; Sht: Sihetang ductile shear zone; Yw: Yiwulüshan

1183   massif; LY–QL: Lingyuan–Qinglong area; LD: Liaodong Peninsula.

**Table 1.** The results of AMS measurements for Queshan, Kunyushan, Yuangezhuang and Sanfoshan plutons. Lat: latitude, Long: longitude, N: the number of cylinders measured in each site, Km: mean magnetic susceptibility, $P_J$: anisotropy degree, T: shape parameter, $K_1$ and $K_3$: magnetic lineation and pole of magnetic foliation, respectively, Inc: inclination, Dec: declination, $\alpha_{95max}$ and $\alpha_{95min}$: Jelinek's statistic confidence at 95% level (Jelinek, 1981) in degrees, KYS: Kunyushan pluton, QS: Queshan pluton, SFS: Sanfoshan pluton, YGZ: Yuangezhuang pluton.
