Key Points:

- Active seismic methods image the Semail ophiolite and broadly constrain the eastern extent of the Arabian continental margin
- Evidence of deep crustal root beneath the UAE-Oman mountain range from Virtual Deep Seismic Sounding
- Folding and thrusting developed during obduction of the Semail ophiolite may have thickened the crust by 16 km

Abstract

The Semail ophiolite, a thick thrust sheet of Late Cretaceous oceanic crust and upper mantle, was obducted onto the previously rifted Arabian continental margin in the Late Cretaceous, and now forms part of the United Arab Emirates (UAE)-Oman mountain belt. A deep foreland basin along the west and SW margin of the mountains developed during the obduction process, as a result of flexure due to loading of the ophiolite and underlying thrust sheets. The nature of the crust beneath the deep sedimentary basins that flank the mountain belt, and the extent to which the Arabian continental crust has thickened due to the obduction process are outstanding questions. We use a combination of active- and passive-source seismic data to constrain the stratigraphy, velocity structure and crustal thickness beneath the UAE-Oman mountains and its bounding basins. Depth-migrated multichannel seismic-reflection profile data are integrated in the modelling of traveltimes from long offset reflections and refractions, which are used to resolve the crustal thickness and velocity structure along two E-W onshore/offshore transects in the UAE. Additionally, we apply the virtual deep seismic sounding method to distant earthquake data recorded along the two transects to image crustal thickness variations. Active seismic methods define the Semail ophiolite as a high-velocity body dipping to the east at 40-45°. The new crustal thickness model presented in this work provides evidence that a crustal root is present beneath the Semail ophiolite, suggesting that folding and thrusting during the obduction process may have thickened the crust by 16 km.

1 Introduction

The complex structure and rocks of the UAE-Oman mountain belt (Figure 1) have been crucial for the understanding of fundamental questions related to ophiolite obduction and mountain building processes (e.g., Glennie et al., 1974; Searle and Cox, 1999; Searle, 2019). For example, the well exposed thrust sheets of oceanic crust and upper mantle of the Semail ophiolite have helped decipher the composition of oceanic

lithosphere, and investigate how more dense oceanic lithosphere can be emplaced onto more buoyant continental margins. Metamorphic soles accreted beneath the mantle sequence peridotites, exposed in tectonic windows beneath the ophiolite, have provided important clues for subduction initiation (Rioux et al., 2016). Folded and thrusted granulite facies meta-sedimentary rocks exposed in the Bani Hamid thrust sheet have been key for making inferences on how the lower continental crust deforms, and was buried to depths of ca 30-40 km and then exhumed (Searle et al., 2014, 2015). Unsurprisingly, the Semail ophiolite (Glennie et al., 1973; Lippard et al., 1986), largely considered as the finest example of its kind, has been the focus of numerous petrological, geochemical, thermobarometric and structural studies (e.g., Tilton et al., 1981; Boudier et al., 1995; Searle & Cox., 1999; Rioux et al., 2013; McLeod et al., 2013, 2016; Searle et al., 2014, 2015; Ambrose & Searle, 2019).

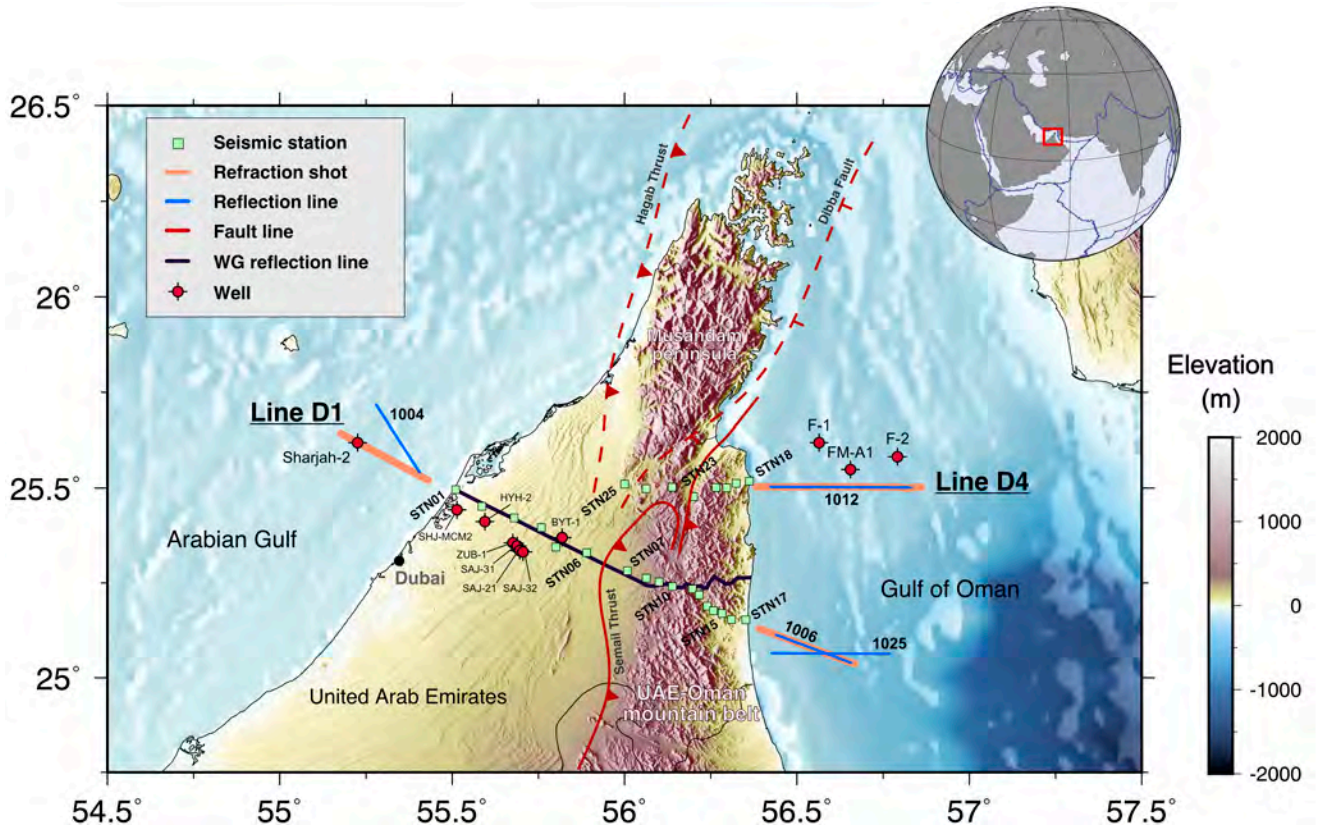

Over the past 50 years or so, geologists have concentrated research on the Semail ophiolite, particularly on its original tectonic setting and processes operating during its emplacement onto the UAE-Oman continental margin. However, comparatively little has been done towards inferring deep crustal structure, especially the geometry and geophysical signature of the ophiolite through integrated approaches, whereby datasets from different disciplines are exploited to infer a comprehensive interpretation. Extensive hydrocarbon exploration efforts, mainly in the form of shallow reflection profiles, have allowed the sedimentary sequences in the foreland basins (situated to the west of the mountain range) to be mapped in high detail. In contrast, the deep structure of the UAE-Oman mountain range is less well known due to a lack of deep, high-quality seismic data, commonly obstructed by the high velocity screen associated with the ophiolite that renders imaging of the underlying structure extremely problematic. Particularly in the relatively less explored eastern offshore, where direct geological observations are restricted by the marine environment, geophysical methods can provide valuable insights into whether the ophiolite is rooted or detached from Tethyan oceanic lithosphere in the Gulf of Oman (Ali et al., 2020).

80 Previous deep seismic reflection studies have attempted to illuminate the crustal
81 structure of the UAE. On behalf of the Ministry of Energy of the UAE, WesternGeco
82 has acquired four deep seismic profiles: two broadly orthogonal and two parallel (one
83 in the middle of the mountains and another along the axis of the foreland inland) to the
84 mountain range. Interpretations on corresponding time-migrated reflection profiles and
85 further processing by Naville et al. (2010) and Tarapoanca et al. (2010) provide
86 meaningful information on the foreland basin and allochthonous structure. However,
87 sub-ophiolite structure, including the present-day Moho, are not adequately resolved
88 and did not allow any interpretation to be carried out at larger depths. Ravaut et al.
89 (1997), and more recently Ali & Watts (2009); Ali et al. (2017), used Bouguer gravity
90 anomalies to broadly delineate the 2-D spatial extent of the Semail ophiolite. In these
91 cases, the lack of seismic constraints was a major obstacle to the creation of a robust
92 crustal model.

93 Great strides have been made with a new interdisciplinary study (Ali et al.,
94 2020), consisting of onshore/offshore active and passive seismic methods, potential
95 field modelling and surface geological mapping. The study of Ali et al. (2020) has been
96 instrumental in probing the crustal structure of the UAE, allowing detailed inferences
97 about ophiolite structure, foreland basins and the lower crust to be made. Although the
98 use of receiver function analysis together with gravity modelling has allowed first-order
99 constraints to be placed on the crustal thickness beneath the transects, limitations of the
100 methods (e.g., due to the presence of thick sedimentary basins, steeply dipping Moho,
101 presence of strong crustal heterogeneities in the crust) prevented the completion of an
102 accurate depth-to-Moho model. Additionally, there is still uncertainty as to how far the
103 crust of the Arabian passive margin extends into the offshore, and therefore the nature
104 of the crust that underlies the Gulf of Oman.

105 In this paper, we combine active and passive seismic data to reconstruct the
106 crustal structure across two transects orthogonal to the UAE-Oman mountain range. We
107 present a series of new depth-migrated reflection images from the Gulf of Oman and

108 the Arabian Gulf, with a more in-depth analysis of the wide-angle seismic profiles
 109 presented in Ali et al. (2020). Our new depth-to-Moho estimates are obtained by
 110 exploiting a recently developed passive-seismic method (Virtual Deep Seismic
 111 Sounding - VDSS), which is capable of producing a well-constrained and substantially
 112 improved crustal-thickness model where receiver function has shown significant
 113 limitations.

115 **Figure 1:** Location map of the study area. Green squares are the broadband seismometers used in the
 116 experiment. Stations are progressively counted from west to east along Line D1 (STN01 to STN17) and from
 117 east to west along Line D4 (STN18 to STN25). Coloured lines offshore the UAE show multichannel seismic
 118 profiles (blue lines) and wide-angle refraction and reflection profiles (orange lines) acquired by R/V Hawk
 119 Explorer. The main tectonic structures are highlighted with red lines. Location of the wells are taken from
 120 WesternGeco Report (2005). The inset in the upper-right corner shows the location of the UAE along with the
 121 main plate boundaries in blue.

122

123 **2 Tectonic Setting**

124 Our knowledge about the composition of the Arabian Platform basement
 125 (eastern Arabia) has been largely inferred from a few scattered inliers in Oman

(Mecolli et al., 2006), and volcanic and sedimentary exotic clasts embedded in intruded salt domes offshore Abu Dhabi (Arabian Gulf), which indicate Ediacaran and Cryogenian ages (Thomas et al., 2015). Despite the extensive lack of basement exposure in eastern Arabia, it is thought that continental growth, possibly via magmatic accretion, has shaped the Arabian Platform architecture (Whitehouse et al., 2016; Alessio et al., 2018; Pilia et al., 2020b).

In the early Paleozoic, the UAE was located in the southern hemisphere on the northern part of the supercontinent Gondwana, facing the Paleotethys Ocean. From Early Permian to Early Jurassic, the northern Gondwana passive margin was subject to multiple rifting events. Rifting commenced in the early Permian and by the Middle Permian an extensive carbonate platform was developed along the entire continental margin, with a general absence of magmatic material. A few rift-related alkali basalt sills were intruded into the early Tethyan oceanic domain preserved in the Hawasina and Haybi complexes structurally beneath the Semail ophiolite (Searle, 2007). Middle Triassic-Early Jurassic extension was accompanied by voluminous transitional-tholeiitic volcanism that culminated with the continental breakup of the Cimmerian Terranes, and the formation of the new Neotethyan ocean (Glennie et al., 1973; Searle et al., 1980). While the Cimmerian terranes drifted away from the Arabian margin and were eventually accreted onto Eurasia, seafloor spreading continued in the Neotethys until the Cretaceous, and beyond. From mid-Permian to mid-Cretaceous, the UAE-Oman margin was a mature carbonate-dominated rifted margin. The obduction of the Semail ophiolite from the Tethyan ocean onto the continental margin since Cenomanian time marked the ending of rifting and the onset of compressional tectonics. During the Cenomanian (Tilton et al., 1981), between 96.1 and 95.5 Ma (Rioux et al., 2013), the Semail ophiolite formed at a fast-spreading center above a shallow northeast-dipping subduction zone (Searle and Malpas, 1980; Pearce et al., 1984; Lippard et al., 1986; Rioux et al., 2016). From 95 to 70 Ma, a series of thrust sheets (including, from structurally lowest to highest position, the Sumeini, Hawasina and Haybi complex

allochthonous sheets, along with sub-ophiolitic metamorphic rocks, oceanic crust and upper mantle of the Semail ophiolite) were progressively emplaced from northeast to southwest onto the subsided Arabian passive continental margin (Glennie et al., 1973; Searle & Cox, 1999). The underthrusting leading edge of the Arabian passive margin constitutes the melt source of leucogranite dykes that intruded the wedge of the Semail ophiolite mantle sequence, as observed in the UAE (Rollinson, 2015; Searle et al., 2015). It is possible that following ophiolite emplacement the downgoing Arabian continental margin reached a maximum depth of 80-100 km, as indicated by the presence of eclogites exposed only in the As Sifah region, SE of Muscat (Searle et al., 2004). In the UAE part of the mountain belt, the mantle sequence is also cut by a thrust slice of folded, high-temperature, granulite-amphibolite facies rocks (Bani Hamid) that has been exhumed by an out-of-sequence thrust (Searle et al., 2015). The exhumed Bani Hamid granulite facies rocks suggest that the lower crust of the UAE-Oman mountain range may have a similar composition. As pointed out by Ambrose & Searle (2019), despite substantial along-strike geochemical and petrological variability of the ophiolite from Oman to the UAE, there is no need to advocate a distinct tectonic history of the ophiolite.

A natural consequence of the emplacement of the ophiolite load was flexure of the pre-existing underlying rift margin and formation of a foreland-type basin, the Aruma basin (Patton & O'Connor, 1988; Ali & Watts, 2009). Thin-skinned deformation dominated the emplacement process, leaving the underlying Mesozoic shelf sediments relatively undeformed. Following the end of the obduction process in the Early Maastrichtian, a deep sedimentary basin formed in the Gulf of Oman, following subsidence and transgression. A compressive tectonic regime promoted by the opening of the Red Sea, and culminating with continental collision in the Zagros mountains, is affecting the current geological evolution of the region. Early effects of the collision can be seen in the Musandam peninsula, where the Oligocene-early Miocene thrusting along the Hagab thrust records initial crustal thickening.

3 Data and Methods

Multi-Channel Seismic (MCS) reflection and Wide-Angle (WA) refraction data were acquired in July 2014 as part of an integrated active and passive seismic, geological mapping and potential field experiment in the UAE (Pilia et al., 2020a, Ali et al., 2020). The experiment, extending from the Arabian Gulf to the Gulf of Oman, was designated to image the deep crustal and upper mantle structure of the northeastern margin of the Arabian Plate, including the UAE-Oman mountain belt and its foreland basins. The focus here is on two active- and passive-source E-W transects (Line D1 and D4), augmented by a number of depth-migrated reflection lines interpreted using well ties (Figure 1). One profile runs for ca 160 km from the Arabian Gulf to the Gulf of Oman across the Musandam peninsula (Line D1), while another extends for approximately 80 km from the UAE-mountain belt to the eastern offshore in the Gulf of Oman (Line D4).

Seismic reflection data were acquired using the commercial seismic ship M/V *Hawk Explorer*. Shots from a 5420 cubic inches (88 liters) airgun array were fired every 20 seconds and recorded for 15 seconds by a 408 channel (1 ms sampling rate), 5-km-long streamer.

A larger source array and greater shot intervals enable high signal-to-noise ratio and deeper travel time picks for wide-angle data. In this case, the source was equipped with four arrays of 12 air guns (7060 cubic inches, 116 liters) towed at 6 meters depth. A total of about 900 air gun shots were fired offshore (400 for Line D4 and 500 for Line D1 equally distributed between the Arabian Gulf and Gulf of Oman) at 50-second time interval (equal to 90 meters - controlled by differential GPS). Air gun shots were then recorded on land by a total of 25 broadband three-component seismometers. Data quality is variable but generally good, allowing arrival identification up to about 70 km offset.

Land stations used for the active shots offshore were separately operational for a year to record passive seismic data (2015 for Line D4 and 2016 for Line D1).

3.1 Active source data processing

We conducted seismic processing for the reflection lines up to pre-stack time migration using ProMax and Seismic Unix. WesternGeco performed final pre-stack processing and conversion of Two-Way Travel Time data to depth using in-house software. The profiles we present here are pre-stack depth-migrated (Figure 2). The processing flow steps included: removal of swell noise and seismic interference noise attenuation, frequency-wavenumber filter in shot domain, true amplitude recovery (spherical divergence correction and exponential gain correction), deterministic water layer demultiple and radon demultiple, anisotropic Kirchhoff pre-stack time migration. This was followed by anisotropic reflection tomography and Kirchhoff pre-stack depth migration. In Figure 2 we show the final uninterpreted and interpreted depth-migrated profiles.

Since the land stations were continuously recording during the wide-angle experiment, the exact timing of the airgun shots was used to cut the seismic records into separate traces of 40 seconds length, after which we assembled them into receiver gathers. After conversion of the gathers to SEG-Y format, the processing included the application of: i) frequency filtering using a band-pass Butterworth filter (2-4-13-15 Hz), ii) automatic gain control, iii) a coherency filter to enhance the visibility of different phases and iv) a linear velocity reduction to ease visibility of seismic arrivals, especially those reflected from the Moho discontinuity (Figure 3).

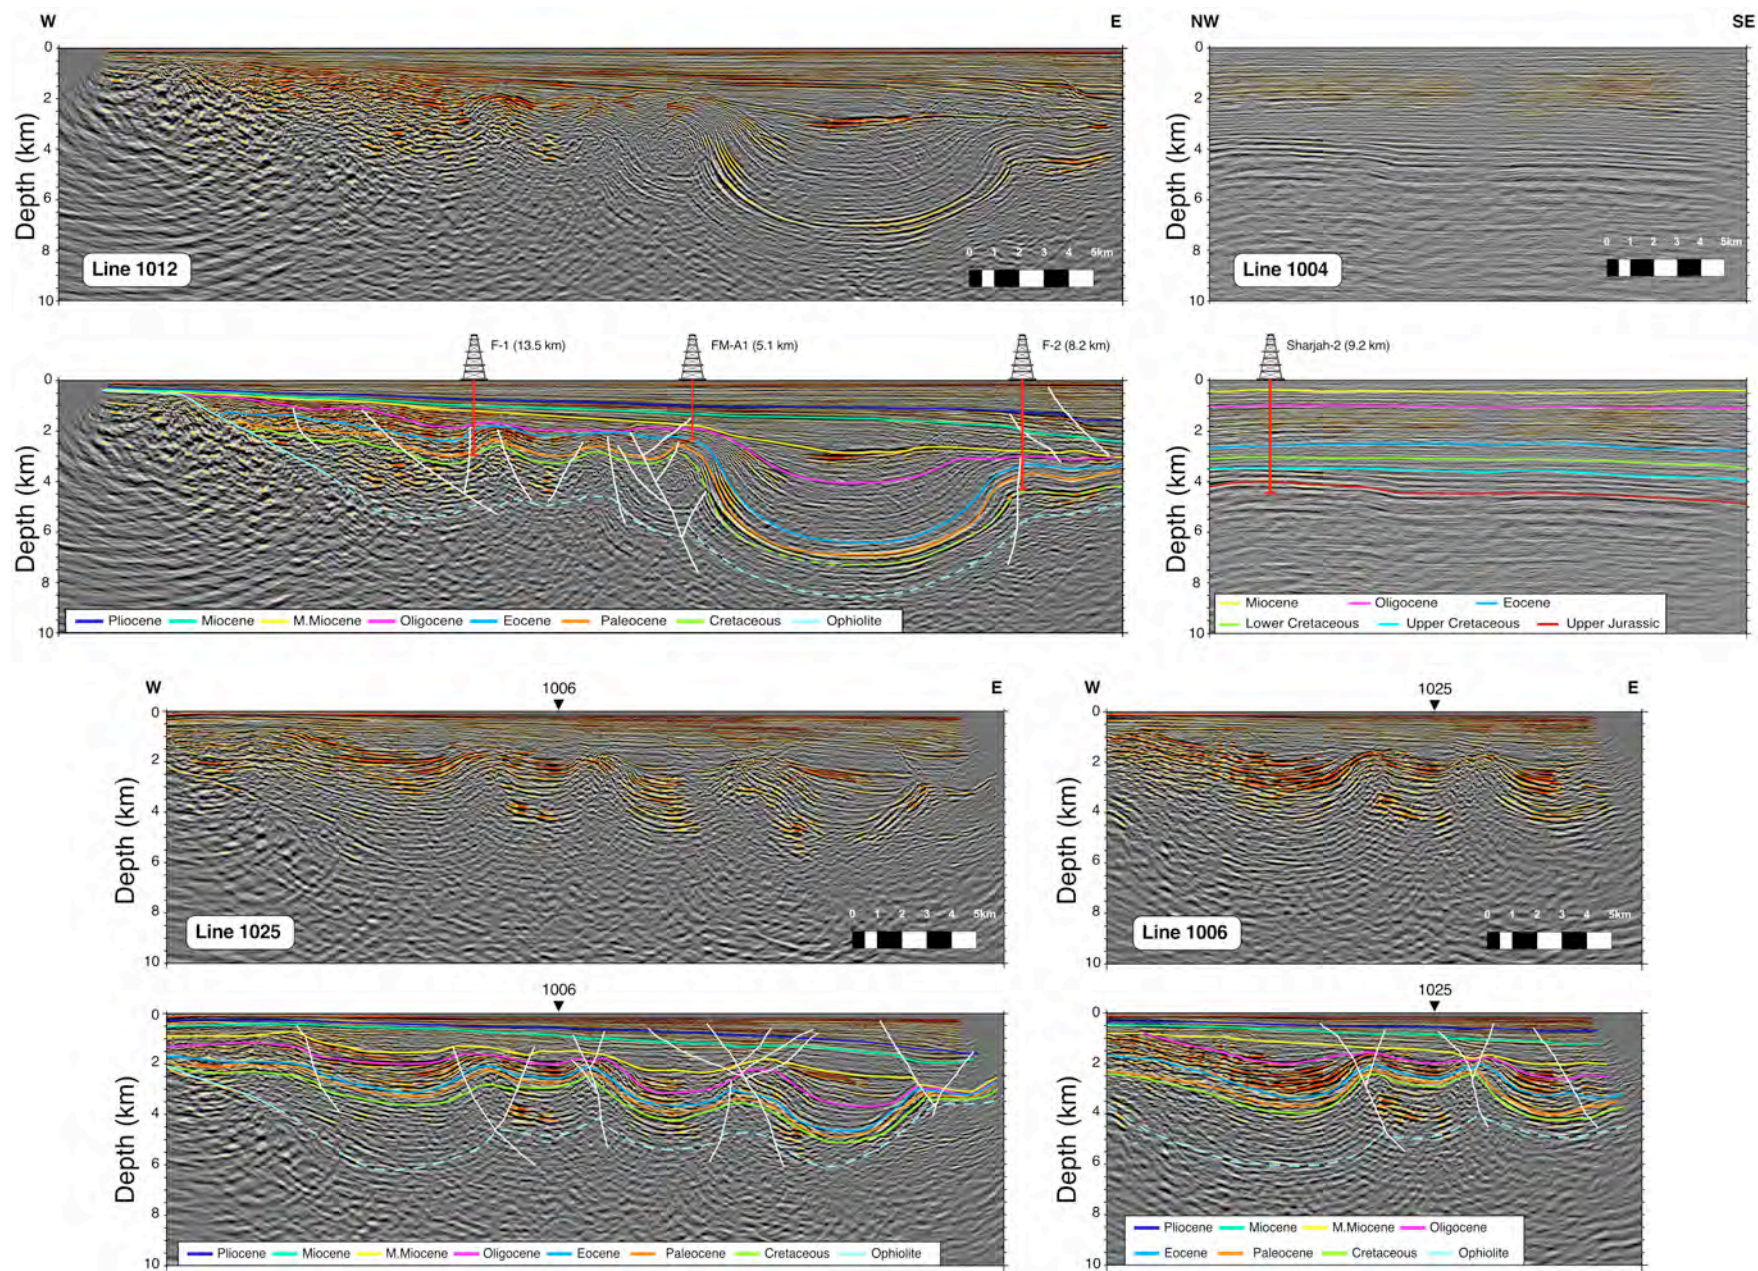

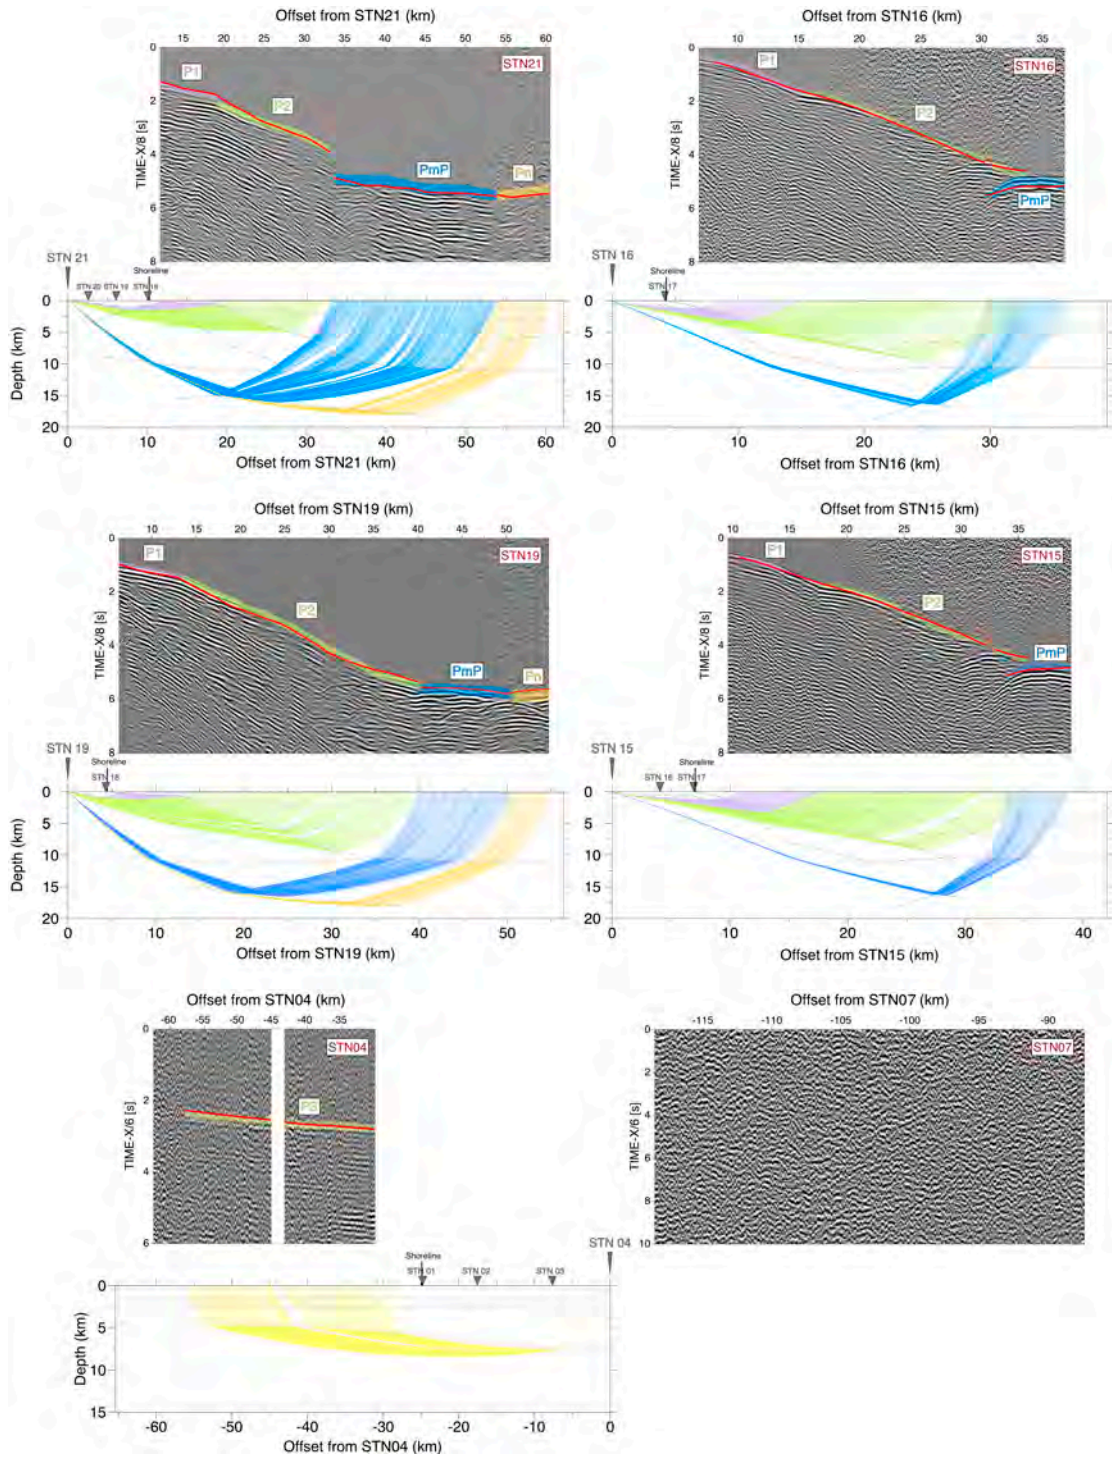

Figure 2: Pre-stack depth-migrated images. Lines 1012 and 1006 are coincident with the eastern offshore portions of Line D1 and D4, respectively. Coloured lines mark prominent reflectors and interpreted stratigraphy tied to well F-1, FM-A1 and F-2 (red vertical lines). White lines are interpreted faults (positive flower structure). Coloured horizons are dashed where uncertain. Location of the seismic transects is shown in Figure 1.

Seismic arrivals are picked by hand on the receiver gathers (unfiltered where possible). We recognized intra-crustal refractions (P1, P2), possible Moho reflections (PmP) and upper mantle refractions (Pn) from the shots in the Gulf of Oman (see STN 15, STN16, STN19 and STN21 in Figure 3). Upper crustal refractions P3 were recorded from sources located in the Arabian Gulf. Phase identification from the western extension of Line D1 in the Arabian Gulf was considerably harder as the data display relatively poorer quality. This is likely because of the sandy nature of the terrain where seismic sensors were deployed. Indeed, the presence of thick sand dunes significantly alters the seismic signal due to the high impedance contrast between sand dunes and underlying formations, reverberations within the dunes, elastic attenuation and topographic scattering, which ultimately produce seismic records characterized by a low signal to noise ratio. Moreover, for environmental reasons, we were not able to use active sources onshore, with the consequence that we could not obtain a reversed dataset. Despite careful analysis and inspection of the filtered and unfiltered seismic sections, we did not find evidence for lateral continuity of seismic arrivals at STN07 (from airgun shots in the Arabian Gulf), which is the farthest station that recorded usable data from the Gulf of Oman (see Figure 3). STN24, STN25 and STN14 did not record usable data due to a timing issue with the GPS. Depending on offset, picking uncertainty was assumed to range from 0.05 to 0.1 seconds for P1 arrivals, 0.10 to 0.15 for P2 and P3 arrivals, and 0.15 to 0.2 for PmP and Pn.

After assembling the travel-time picks from the receiver gathers, the 2-D ray tracing software Rayinvr (Zelt & Smith, 1992) was used to model the wide-angle seismic data, following a layer-stripping approach (Zelt, 1999). Additional geological

260 and geophysical constraints were incorporated in the modelling procedure where
261 available.

3.2 Passive source: virtual deep seismic sounding

Less conventional than wide-angle active-seismic experiments, Virtual Deep Seismic Sounding (VDSS) is a relatively new approach that uses wide-angle reflections from passive sources (i.e., earthquakes). The method employs the SsPmp phase (Figure 4), an incident S-wave from epicentral distance between 30°-50° that reflects under the free surface and converts to P-wave, which subsequently reflects off the Moho (Tseng et al., 2009). The S-to-P under-side reflection is the virtual source for the wide-angle reflection bouncing from the crust-mantle boundary. One of the key advantages of the method is that the P-wave reflection from the Moho is post-critical. As such, the SsPmp phase is characterized by a high signal-to-noise ratio. However, because of the total internal reflection from the Moho, the SsPmp phase undergoes a phase shift that varies with epicentral distance when compared to the Ss arrival. A proxy for crustal thickness can be calculated from the arrival time of the SsPmp phase relative to the incident S wave, as in the following equation:

$$T_{SsPmp-Ss} = 2H (V_p^{-2} - p_\beta^2)^{1/2} \quad (1)$$

where H is the crustal thickness, V_p is the average crustal velocity and p_β is the ray parameter, or horizontal slowness, of the incident S-wave, determined from the known source-receiver geometry and the ak135 velocity model (Kennett et al., 1995). Below we describe the procedure adopted to process the VDSS dataset, which is largely based on the implementation proposed by Thompson et al. (2019).

We analyze broadband waveforms collected by the seismic sensors distributed along segments D1 and D4 across the UAE-Oman mountain range and foreland area (Figure 1). We select seismic sources with moment magnitude larger than 5.0 in the epicentral

293 distance range 30° - 50° , resulting in a total of 156 earthquakes (Figure 4). Traces
 294 associated with the S-arrival time are windowed using predictions from the global
 295 reference model ak135 (Kennett et al., 1995). Pre-processing involves removing the
 296 instrument response from the event data and apply a second-order zero-phase
 297 Butterworth filter with corner frequencies of 0.05 and 0.5 Hz. Horizontal components
 298 are then rotated into radial and tangential components. In order to remove source-
 299 wavelet effects (e.g., source-side scattering and source time-function complexities) we
 300 apply the source normalization method of Yu et al. (2013). This allowed us to account
 301 for all seismic events within the SsPmp epicentral distance limits, regardless of their
 302 focal depths. Therefore, we calculate the angle necessary to rotate the vertical and radial
 303 component traces into pseudo-S component using the ak135 (see Yu et al. 2013, and
 304 Thompson et al. 2019). These are then deconvolved from the vertical and radial
 305 component VDSS traces using an extended-time multitaper approach (10 sec sliding
 306 window, 75% window overall, 3 Slepian tapers; Helffrich 2006). After this step, vertical
 307 component VDSS traces are visually inspected and selected if they satisfy three main
 308 criteria: i) a prominent Ss arrival centred at time zero; ii) evidence of a stable
 309 deconvolution (i.e., no ringing or unwarranted oscillatory signal); iii) evidence of a
 310 prominent pulse associated with the SsPmp arrival time, and those corresponding to the
 311 precursory Sp and reverberatory SsPmsPmp phases. Expected traveltimes and
 312 waveforms were computed with the aid of synthetic seismograms constructed using the
 313 reflectivity method of Fuch & Müller (1971). For this endeavour, we use a mantle half-
 314 space and a single crustal layer with thickness below each station taken from the
 315 seismically and gravimetrically constrained cross-sections in Ali et al. (2020). The
 316 effective number of retained VDSS traces was on average ten per station, with typically
 317 around 70% of seismograms removed from our dataset to ensure that only high-quality
 318 VDSS traces are included in our computations. As a final check, we also compare
 319 observed and synthetic seismograms (Figure 5). For each station, observed traces are
 320 binned and stacked by slowness bins of 0.2 sec deg^{-1} , allowing a 50 % overlap. We

illustrate two examples in Figure 5: one for STN03, located in the foreland area where the crust is assumed to be relatively thin, and STN10, located in the mountain belt where $T_{SsPmp-Ss}$, and therefore crustal thickness, is expected to be larger. Arrival times of the SsPmp phase appear to be consistent with those estimated using synthetic seismograms, characterised by a clear moveout across the epicentral distance range (or slowness), as observed from the predicted arrival times. It is important to note that the Sp and SsPmsPmp phases are affected by the V_p/V_s ratio within the crust, whereas the SsPmp is only affected by the V_p velocity. This could explain why the precursory and reverberatory phases are slightly off from the arrival time predicted by the synthetic seismograms.

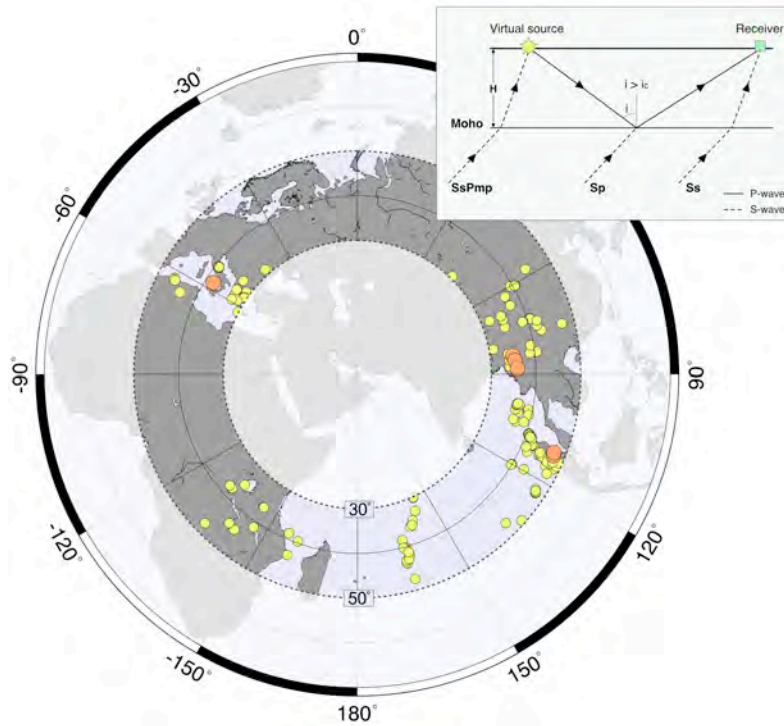

Figure 4: Distribution of passive-seismic sources in the epicentral distance range 30°-50° used to measure the $T_{SsPmp-Ss}$. Yellow and orange dots depict earthquakes with a focal depth smaller and larger than 100 km, respectively. Upper right inset shows a schematic ray diagram of the main phases observed during the analysis of VDSS traces (i is the incident angle at the Moho, i_c is the critical angle).

At this stage, solving Eq. 1 to calculate crustal thickness is not difficult; however, it is important to have a good knowledge of the bulk velocity V_p . To this end,

we make use of insights from other geophysical results to generate an accurate V_p value below each station. In this case, velocities from the wide-angle refraction models are used, although for the vast majority of the stations they constrain the upper and mid crust only. For this reason, lower crustal densities inferred from gravity modelling in Ali et al. (2020) are converted to V_p (Brocher, 2005) to obtain a more complete velocity model of the crust. Finally, the resultant ensemble of depth-migrated 1-D profiles are linearly stacked to produce a summary trace through which the total crustal thickness can be estimated by determining the depth at which the zero-crossing occurs.

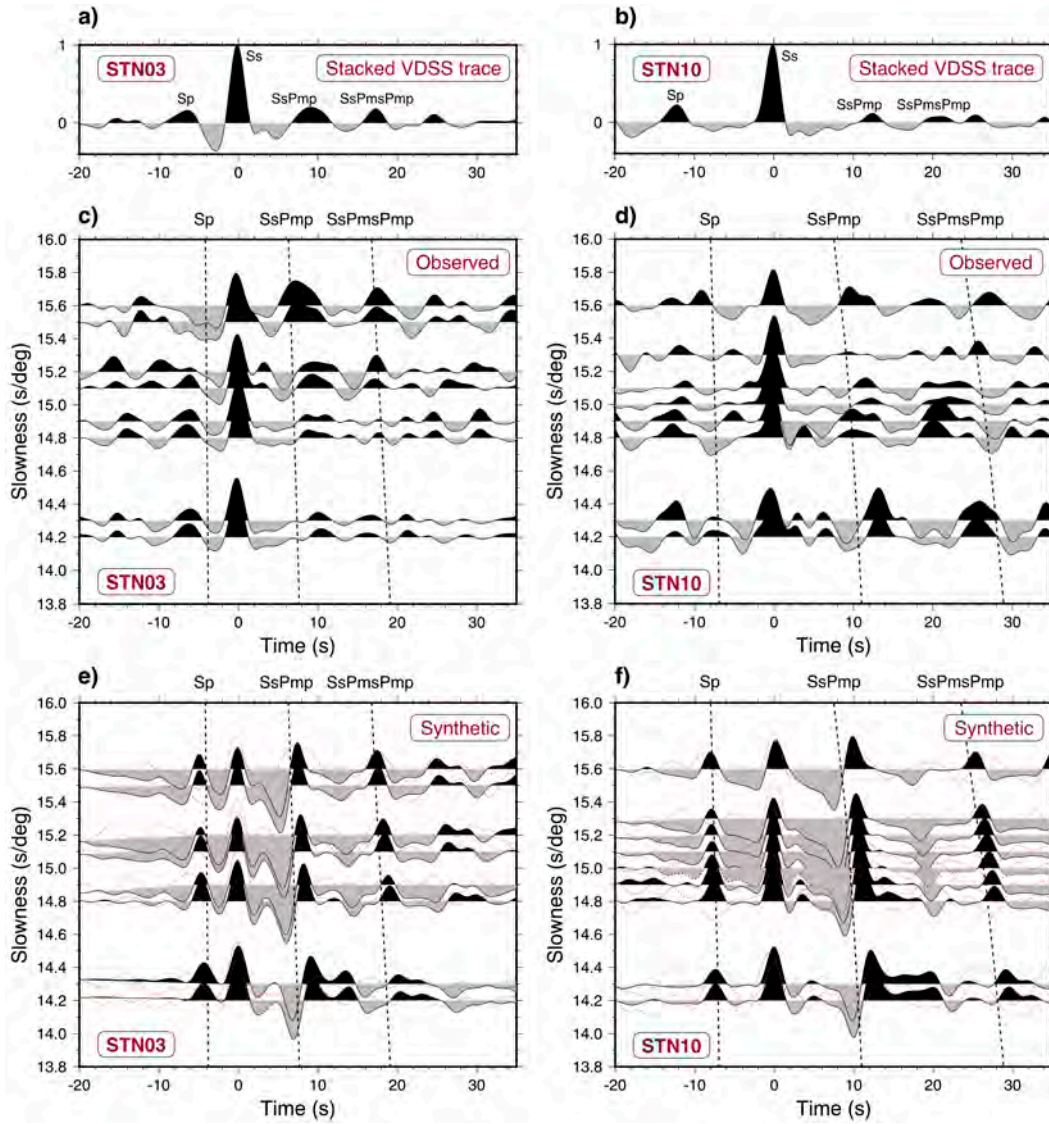

4 Results

4.1 Seismic Reflection and well data

From the narrow continental shelf of Oman in the south to the Makran Accretionary Prism in the north, the Gulf of Oman is dominated by deep-water sediments of the Sohar basin. Three exploration wells (FM-A1, F-1 and F-2 in Figure 1) were drilled in the late 70s and 80s and are at a relatively short distance from profile 1012 (Figures 1 and 2). Well data from FM-A1, F-1 and F-2 are used for seismic ties to the seismic reflection transects in the Gulf of Oman (Figure 2). They appear to mostly penetrate calcareous siltstone and claystone, calcareous claystone with limestone, and sandstone with minor calcareous claystone derived from the rift flank and erosion of the Arabian margin.

Close to the eastern coastline of the UAE, gently dipping reflectors associated with Pliocene and Middle Miocene stratigraphy are observed to a depth of about 500 m, increasing up to 3 km towards the east. Oligocene to Cretaceous units display highly reflective packages, are structurally more complex and onlap a surface with a reasonably more chaotic seismic character in the west, which we attribute to the top of the ophiolite sequence. This major boundary (light blue line in Figure 2) steeply deepens seaward and we are able to accurately trace it up to about 5 km depth; farther offshore and at greater depth, seismic horizons are weakly reflective and difficult to

366 identify. Even though it is not possible to recognise distinct reflective events beneath
 367 the top of the ophiolite sequence, the full overlying sedimentary package is reasonably
 368 well imaged, including a series of possible positive flower structures (white lines in
 369 Figure 2), typically associated with strike-slip faults. Some of these faults appear to cut
 370 through the Pliocene strata and reach just below the seafloor.

371
 372 Figure 5: Two examples of observed (c, d) and synthetic traces (e, f) for STN03 and STN10. a) and b) are
 373 obtained by stacking all available VDSS traces for the respective station. Traces are aligned along the Ss
 374 arrival at time zero. The dashed black lines are the predicted traveltimes for Sp, SsPmp and SsPmsPmp
 375 phases, calculated using a modified version of the ak135 velocity model to include the crustal thickness
 376 estimated with the 1-D migration procedure. Clear moveout of the SsPmp phase is observed across the
 377 slowness range, arriving earlier at large slowness (i.e., shorter epicentral distance). Note the larger arrival
 378 time of the SsPmp phase that characterizes STN10, compatible with a greater crustal thickness. Dashed red
 379 lines are VDSS observed traces that overly the synthetic seismograms.

The only seismic reflection transect acquired in the Arabian Gulf is 1004. This profile is characterised by a somewhat poorer quality but an extremely simple flat-lying stratigraphy and laterally continuous reflectors. Well Sharjah-2 is located about 10 km to the southwest of the seismic profile and has been used to calibrate the reflectors. A single package of intermittent bright reflectors with relatively high P-wave velocity exists between 0.5 and 2.6 km. This defines a layer of Oligocene massive salt.

4.2 Velocity models

Although we cannot image the lower crust due to the length of the multi-channel seismic streamer, layering and thickness of the sediments, as well as the top of the ophiolite inferred from the seismic reflection images are valuable constraints that can be included while modelling the wide-angle seismic dataset. For example, high-resolution water depth, top of the post-obduction Oligocene sediments, and top of the ophiolite body were gathered from the seismic-reflection lines in the Gulf of Oman. Similarly, thickness and velocity of the uppermost layers (up to ca 5 km depth) in the Arabian Gulf are determined from borehole data of well Sharjah-2 (WesternGeco Report) and were not allowed to change during modelling. Additionally, we integrate in our analysis constraints from the time-migrated reflection line of WesternGeco (Figure 6), specifically the trend of stratigraphic interfaces up to the top of the Jurassic. The final P-wave tomographic model was progressively built from top to bottom minimizing the misfit between observed and predicted travel times. We used a total of 2081 and 2207 traveltimes picks for Line D4 and D1, respectively (see Table S1 where we also detail the misfit statistics for the two profiles).

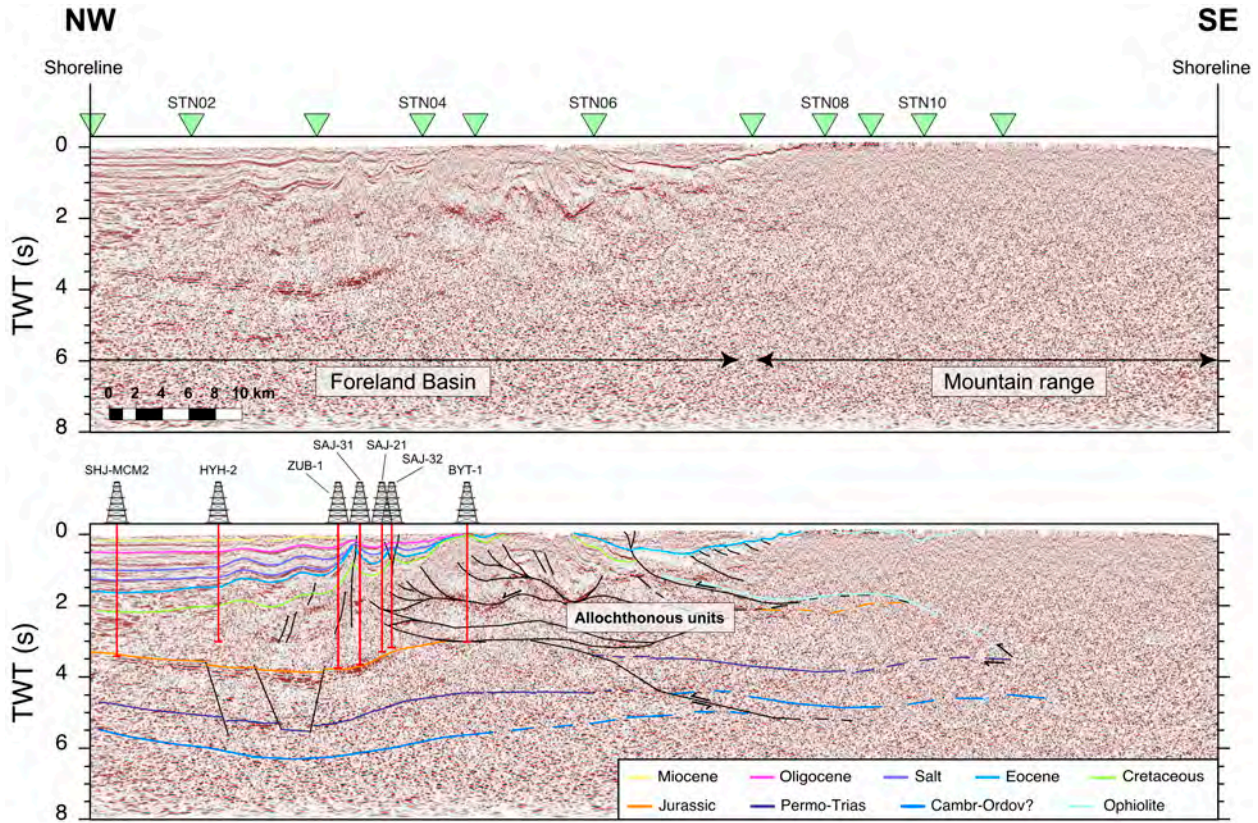

Figure 6: Two-way time-migrated structure profile along line D1 (see Figure 1 for location). Processing and interpretation have been carried out by WesternGeco. Easternmost seismic stations (from STN12 to STN17) are not included in the plot as the reflection profile diverges from our transect in correspondence of STN11.

Figure 7 illustrates the final 2-D P-wave velocity model beneath the UAE-Oman mountain belt and Arabian rifted passive margin. Two distinct domains with different velocity structures appear at approximately both sides of the eastern shoreline from Line D4 and D1. In the eastern regions of the profiles, the upper and mid crust is dominated by a relatively low velocity structure that characterizes the post-ophiolite sediments. The sedimentary package progressively deepens towards the offshore, reaching a maximum thickness of around 10 km, which is somewhat larger than the depth estimated from the depth-migrated reflection line. Post-ophiolite sediments are marked by seismic velocities that gradually increase from 1.8 km s^{-1} near the seafloor to nearly 4.5 km s^{-1} at the base. This is best observed along Line D4, where a greater number of sources in the offshore allows for relatively better constrained velocity structures (see Figure S1 for rayhits). The sediments are underlain by a relatively thin layer that displays seismic wavespeeds exceeding 4.5 km s^{-1} at 11 km depth. This latter

depth marks an interface distinguished by a prominent vertical velocity gradient (velocity increase $>1.5 \text{ km s}^{-1}$), which reveals a layer slightly thicker than 6 km with an average velocity of ca 7 km s^{-1} . The base of the eastern offshore domain is defined by clear reflections from an uneven Moho (see Figure 3), which place the Moho at ca 17-18 km depth on both Line D1 and D4. We observe another substantial velocity change in this part of the model with upper mantle seismic velocities rising up to 8.2 km s^{-1} .

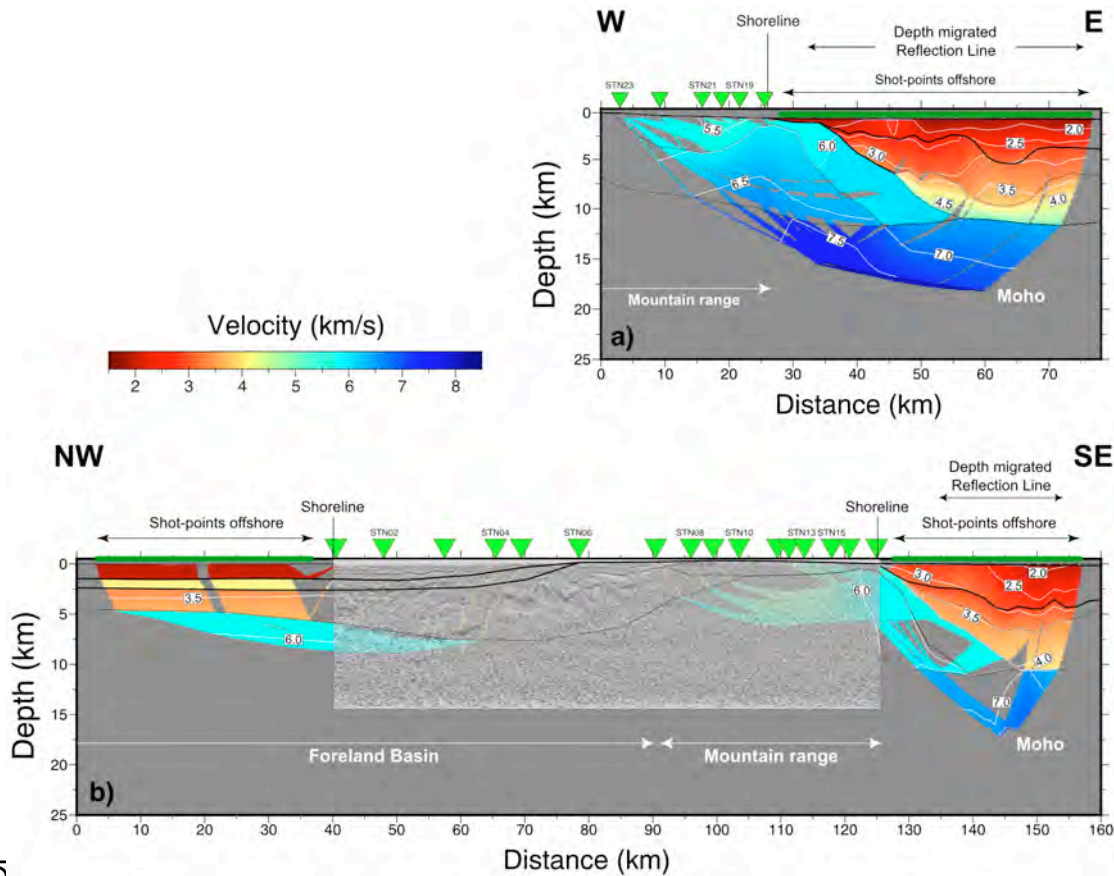

A standout feature of the velocity models is the presence of an elongated structure with a distinct velocity in the range $5\text{-}6 \text{ km s}^{-1}$, which marks the largest lateral velocity contrast ($> 3 \text{ km s}^{-1}$ in places) with the overburden of Cenozoic sediments in the Gulf of Oman. Between 30 and 60 km model distance of Line D4, the tendency for this high-velocity body is to approach the shoreline with a constant angle of $40\text{-}45^\circ$ and a nearly constant thickness of ca 5 km. It appears to dramatically thin and crop out in the vicinity of the shoreline where the velocity has decreased by 0.5 km s^{-1} . It marginally thickens again below the mountain belt with a maximum depth of 3.5 km. We note, however, that the bottom of this feature is not bounded by any reflection and should therefore be viewed with caution (Figure S1). The crust beneath exhibits gradually increasing velocities but reveals extremely high velocities at the base of the model, particularly along Line D4, where velocities up to 7.6 km s^{-1} are modelled. The Moho in Line D4 is gently bulging at middle model distances with laterally homogeneous upper-mantle velocities defined by possible Pn arrivals.

Line D1 is broadly less constrained than Line D4, since it exhibits a considerably less dense ray coverage (Figure S1). This is particularly true at model distance 70-100 km, where in addition to the considerable tectonic complexity of this portion of the transect, the offshore-shots distance from both directions inhibits the recording of good quality arrivals. As observed from MCS line 1004, the western foreland area is laterally homogeneous with relatively undeformed, sub-horizontal layers. The uppermost layers, which show relatively low wavespeed, overlay a layer of

447 $V_p \sim 6 \text{ km s}^{-1}$, constrained by P3 arrivals and associated to upper Jurassic carbonates,
 448 readily identified from the two-way traveltime profile as strong reflectors (Figure 6).

449 4.3 VDSS profiles

450 The differential arrival time between the SsPmp and Ss phases is in the range 6-
 451 11 seconds, implying significant variations in Moho depth across the profiles. As
 452 explain in Section 3.2, VDSS traces have been migrated to depth, with the final crustal
 453 thickness profiles shown in Table S2 and Figure 8 (see also Figures S2 and S3 for
 454 possible back-azimuthal dependence of the results).

45
 456 **Figure 7: Final P-wave velocity model for Line D4 (a) and Line D1 (b).** Green inverted triangles show seismic
 457 stations and dark-green circles offshore correspond to the shoot points for the wide-angle data. Thin black
 458 lines illustrate layer boundaries, while thin white lines are velocity contour intervals (0.5 km s^{-1}). Grey areas
 459 are not covered by seismic rays. STN14, STN24 and STN25 did not record usable data. Time migrated
 460 reflection line D1 (shown in Figure 6) is added in transparency to enhance imaging at mid model distances
 461 where a gap in the wide-angle seismic data is present. Black thick lines are horizons taken from the reflection
 462 images and incorporated during modelling of wide-angle data.

In order to evaluate uncertainties of our crustal thickness measurements, we bootstrap the population of input VDSS traces for each station. We randomly draw 100 samples (allowing repetition) and compute the standard deviation of the bootstrapped samples. Error estimates are typically ± 2 -3 km, as shown with vertical bars in Figure 8. The basic trend of the Moho is to follow the topography. This is apparent from profile D1, where the westernmost part of the profile exhibits a crust-mantle interface of 30 km, gradually increasing to the east in accordance with rising elevation. Moho depth values sharply rise to the east of the Semail thrust (to a maximum of 51 km), mimicking the topography, to decrease again until the easternmost stations.

5 Discussion

5.1 Crustal structure from active seismic methods

Ravaut et al. (1997), and more recently Ali et al. (2017, 2020), have shown that the UAE-Oman mountain belt is characterised by a N-S trending Bouguer gravity anomaly high that correlates with the exposed ophiolite. This is flanked on the western side by a gravity low related to the UAE foreland basin. The gravity high extends offshore but does not provide any insight into whether or not the ophiolite is rooted or detached in the Gulf of Oman. In the study of Naville et al. (2010), seismic velocities and thickness of the ophiolite were investigated by using seismic reflection data acquired by WesternGeco along a profile about 20 km south of Line D4. They determine an average velocity of 6 km s^{-1} close to the coast, which decreases to 5 km s^{-1} when about 20 km inland. They also speculate a thickness of the obducted ophiolite of ~ 5 km when close to the east coast (no constraints are evident from the reflection line in this area) which landward becomes less than 1 km. Tarapoonca et al. (2010) concentrated on the reflection profile that coincides with the onshore section of Line D4. The aim of their study was to elucidate the crustal architecture in the top 10 km and simulate the kinematic evolution of the obduction process. They present a structural interpretation with the Semail ophiolite as thick as ~ 5 km near the shoreline, although

even in this case picking the bottom reflector of the ophiolite proved to be extremely challenging. More recently, Ali et al. (2020) showed that onshore the western part of the Semail ophiolite is relatively thin, thickening to the east (with a dip of 40-45°) where it is ~15 km along the coastline, and that it terminates along a NE-dipping normal fault immediately offshore the UAE. They describe the ophiolite as a body with high density, high magnetic susceptibility and high P-wave velocity.

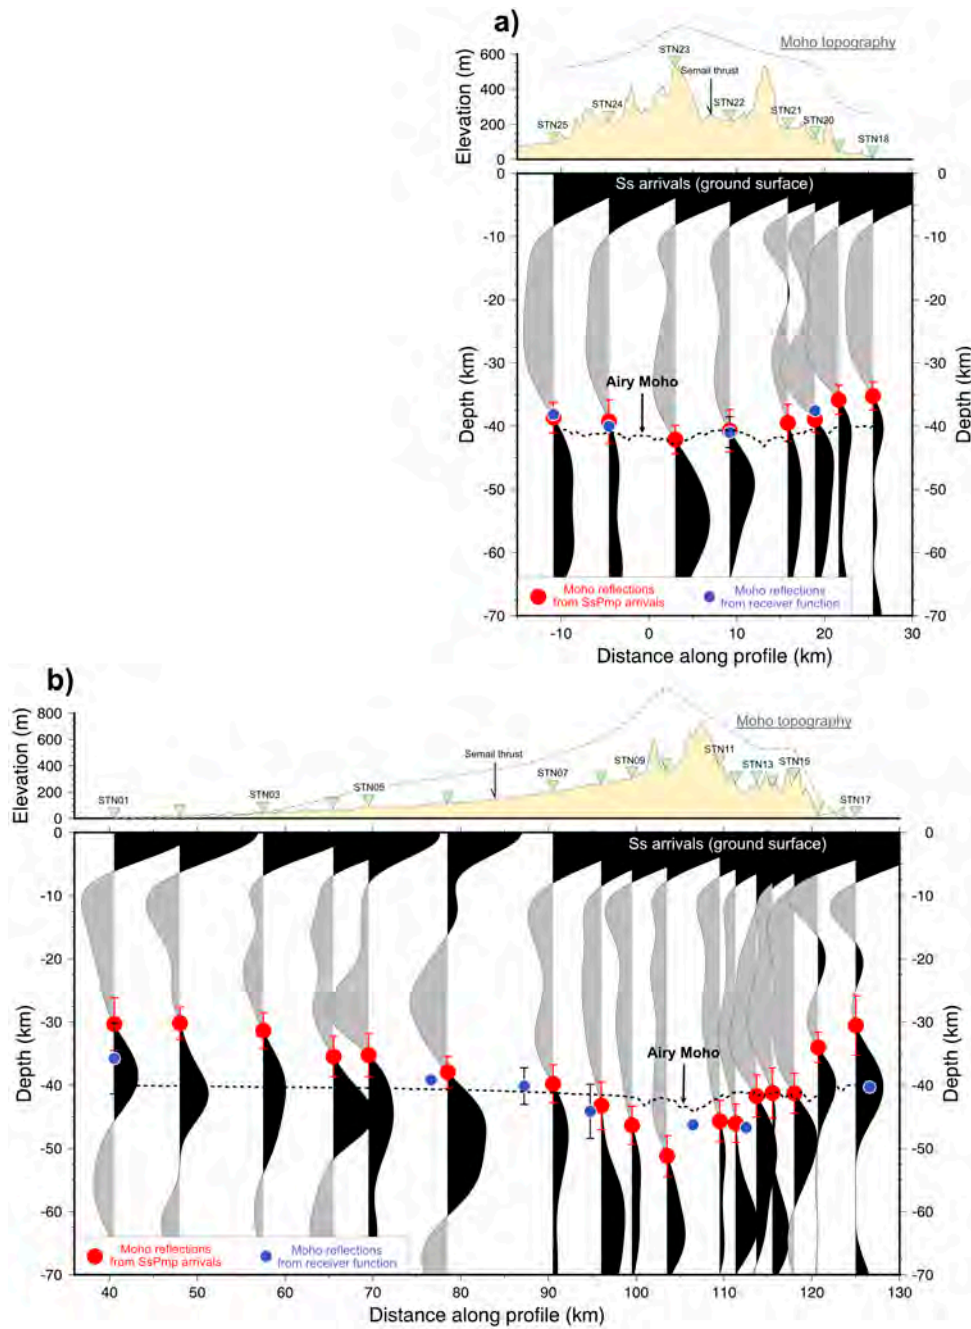

Figure 8: Depth-migrated 1-D reflection profiles constructed using the SsPmp phase. a) Line D4; b) Line D1. Red dots are the estimated crustal-thickness values with relative uncertainties displayed as vertical red bars.

For comparison, receiver-function-derived crustal depths (Ali et al., 2020) are included as blue dots. Topography is shown above each profile. Black dashed lines show the expected depth to Moho assuming an Airy model of isostasy. Grey dashed lines above the topography plots show the smoothed, inverted, seismically constrained Moho to highlight a possible lateral offset between the topographic peak and the crustal root (D1). The offset is not readily visible along Line D4, perhaps due to the fact that our station coverage across the transition from mountain belt to foreland area is more limited.

We interpret the high P-wave velocity feature found in the upper crust of the mountain belt and dipping to the east, as the Semail ophiolite. The 5-6 km s⁻¹ velocity range is typical of sheeted dikes or upper gabbros from ophiolites in the Troodos, Papua New Guinea and Newfoundland. We note that the uppermost section of the oceanic crust (pillow lavas) is not observed anywhere in the UAE, although it is present in Oman. Seismic reflection data (Figure 2), with the aid of several wells, allow us to image the stratigraphy of the broad depositional sedimentary basin underlying the Gulf of Oman. The 4.5 km s⁻¹ velocity contour of Line D4 may be a good local approximation of the depth to Cretaceous basement.

In agreement with Ali et al. (2020), we associate the surface between the ophiolite and sediment infill as a major east-dipping normal fault that probably marks the eastern extension of the Arabian continental crust. Pilia et al. (2020b) used relative arrival-time residuals from teleseismic earthquakes to map the 3-D lithospheric structure of the region and revealed a lithospheric boundary that runs roughly parallel to the coastline in the immediate offshore. Likewise, they associate the velocity anomaly contrast to the western boundary of oceanic lithosphere. In order to gain insights into the nature of the basement under this locality, in Figure 9 we compare the 1-D velocity depth-profile extracted at model distance 61 km along Line D4 with compilations made for extended continental crust (Christensen & Mooney, 1995) and old (age >7.5 Ma as defined in Christeson et al., 2019) oceanic crust formed at fast-spreading centers (Christeson et al., 2019). Our profile finds strong affinity of compressional seismic velocities with reported velocities for oceanic crust for this section of the crust, which are substantially higher than average velocities for extended continental crust at comparable depths. One caveat with this result is that seismic

530 velocities in this portion of the model are not accurately reconstructed, as they are only
531 constrained by unidirectional PmP and Pn arrivals. Overall, our results tend to concur
532 with the conclusion postulated by Ali et al. (2020), in that the Gulf of Oman is underlain
533 by oceanic crust, which is bounded to the west by a normal fault now representing the
534 upper (eastern) contact of the Semail ophiolite. Our interpretation implies that the
535 Semail ophiolite may be detached from in-situ oceanic lithosphere in the Gulf of Oman.

536 One important inconsistency between our velocity models and the interpretation
537 of Ali et. al (2020), as well as the Moho topography shown in Figure 8, lies at mid-
538 crustal depths beneath the mountains and at the continent-ocean transition region.
539 While we find the Moho to be relatively shallow in the Gulf of Oman, a credible
540 observation, if the gravity effect of relatively low density Cenozoic sediments is
541 compensated by the relatively high density of a shallower mantle, it is difficult to justify
542 a present-day shallow Moho (ca 15 km) in the region adjacent to the present-day
543 coastline, as suggested by the active source seismic data acquired along Line D4 (Figure
544 7). Such interpretation would be in stark contrast with evidence provided from potential
545 field data modelling and crustal thickness derived from passive seismic methods, which
546 place the base of the obducted crust and upper mantle at 23 km depth and the present-
547 day Moho at potentially 30 km. Yet, we recognise high-quality wide-angle seismic
548 reflections of large amplitude at most receiver gathers situated in the east, where they
549 exhibit large ($> 7 \text{ km s}^{-1}$) apparent velocities. Intriguingly, the 7.0 and 7.5 km s^{-1}
550 velocity contours, as well as the Moho seem to approach the coastline from the east
551 with the same angle as the Semail ophiolite. Rather than calling upon a reflector within
552 the oceanic lithosphere itself, one conjecture is that an older Moho associated with the
553 ophiolite thrust-sheet complex may exist.

Figure 9: 1-D velocity-depth profile extracted from the final velocity model at model distance 61 km of Line D4 (dashed red line). We compare our velocity profile with the range of typical velocity profiles for “old” oceanic crust (defined by Christeson et al., 2019 as older than 7.5 Ma) formed at fast-spreading centers (grey 1-D profiles), and extended continental crust (light blue line with uncertainties).

5.2 On the crustal thickness beneath the UAE-Oman mountain belt

Crustal receiver functions computed by Ali et al. (2020) provide key evidence for Moho topography beneath Line D1 and D4. They focus primarily on the conversion of teleseismic P-waves to crustal S-waves across the Moho (Pms) and its multiples, using an assumed average crustal velocity of 6.5 km s^{-1} for depth conversion, and H-k stacking. In relatively high-frequency (0.05-4 Hz), conventional receiver function studies, complex tectonic structure promoted by orogenic episodes has the undesirable effect of disguising P-to-S energy converted at the Moho. Challenges chiefly stem from

the fact that the Pms conversion emerges as a small amplitude event, which can be hard to perceive if reverberations in the sedimentary package, strong intra-crustal reflections, thick crust, and a transitional crust-mantle boundary are present. These factors may have hindered the ability of receiver function to define the crustal thickness at several localities along Line D1 and D4 (Figure 8). Conversely, in VDSS studies, the P-to-P conversion from the Moho is post-critical (i.e. total internal reflection of the SsPmp phase) with a low frequency content that suppresses intra-crustal reflectors. Thus, the advantage is that strong SsPmp arrivals can be detected in complex tectonic settings; this enable us to provide robust observational constraints on the overall Moho configuration across both transects (Table S2 and Figure 8), even in regions where receiver function failed to supply reliable results. That said, a comparison of the Moho depth estimates shown here with those produced by Ali et al. (2020) shows good general agreement, although they may have underestimated the maximum crustal root beneath the mountain range by ca 5 km. One reservation to bear in mind when comparing the two sets of results is that the Moho signature is influenced by different structures due to the different ray geometries used for the two methods.

One important result that emerges from this study is the 20 km thickening of the crust (profile D1) that occurs across a limited region beneath the ophiolite, along the mountain belt (~60 km). Interestingly, the most abrupt deflection of the Moho topography appears immediately to the east of the Semail thrust and is slightly offset landward with respect to the highest elevations of the mountain range. A similar trend has been observed in the Zagros mountains (Paul et al., 2006), where the Moho exhibits a deflection of 25 km in 160 km distance, with the largest crustal thickness measured beneath the lower elevations of the Sanandaj–Sirjan zone. Similarly, Kummerow et al. (2004) revealed a 20 km step in crustal thickness over a distance of 90 km in the eastern Alps.

Permian to Early Cretaceous rifting and stretching of the Arabian continental margin was followed by considerable thickening through folding and thrusting

596 associated with emplacement of the ophiolite since the Cenomanian (ca 96 Ma), along
597 with the allochthonous units structurally beneath (Hawasina and Haybi complexes),
598 onto Arabian continental crust (Searle et al., 2014, 2015). A way to test isostasy in
599 mountain belts is to compare the seismically-constrained crustal thickness directly with
600 predictions from the Airy model. In Figure S4 we show the computed Airy depth-to-
601 Moho using topography data from model SRTM90 (onshore), assuming densities of
602 1030, 2800 and 3300 kg m⁻³ for water, crust, and mantle, respectively. As a proxy for
603 the unstretched crustal thickness of the Arabian Platform (zero-elevation) we adopt the
604 Moho depth found in Tkalčić et al. (2006) and Kaviani et al. (2020), which place the
605 crustal-mantle interface at 40 km. The depth to the Airy Moho along transects D1 and
606 D4 is shown as a dashed line in Figure 8. The amount of shortening implied by the Airy
607 model for an elevation of 700 meters would be nearly 10%, assuming the densities and
608 zero-elevation crustal thickness described earlier. Figure 8 shows that there is a major
609 departure between the calculated Airy Moho and the observed seismic Moho beneath
610 the mountain belt and in the foreland area. This indicates that the seismically
611 constrained Moho cannot be explained by an Airy model of isostasy. More importantly,
612 the crustal root appears to be laterally offset landward of the topographic peak,
613 suggesting that the difference between the calculated Airy Moho and the seismically
614 constrained Moho is due, at least in part, to flexure of the Arabian rifted margin by
615 ophiolite loading. In order to understand the fundamental effects that the obduction
616 process has exerted on the crustal thickness, we consider the thinned, pre-obduction
617 crustal thickness. Ali & Watts (2009) used gravity anomalies, seismic reflection profiles
618 and exploratory wells to find a stretching factor of the crust underlying the UAE $\beta=1.3$.
619 Using the estimated crustal thickness of 40 km for the Arabian Platform unstretched
620 crust and applying a stretching factor β of 1.3, the crust following extension and prior
621 to the ophiolite emplacement might have been as thick as 30 km, which is congruent
622 with the depth-to-Moho estimates inferred from the westernmost stations of Line D1.
623 Additionally, Ali et al. (2020) predict that a flexural depression of the pre-existing rifted

margin due to the ophiolite load by at least 5 km. Taking these factors into account, it is possible that folding and thrusting during obduction of the Semail ophiolite has thickened the crust beneath the mountain belt by about 16 km (up to 51 km), thereby creating a substantial crustal root beneath the mountains. Pervasive shortening of the crust beneath the ophiolite is manifest in the Late Cretaceous isoclinal folds in the Bani Hamid granulites, which have been exhumed on one or more thrusts from lower crustal depth (Searle et al., 2014, 2015).

6 Conclusions

A standout feature of our final compressional velocity model is the presence of a relatively high-velocity region ($5\text{--}6\text{ km s}^{-1}$) extending from beneath a thick sediment accumulation in the Gulf of Oman to the surface in the UAE-Oman mountain range. We interpret this as evidence for the proposed geometry of the Semail ophiolite. A major, east-dipping normal fault bounds the eastern limit of the ophiolite, as inferred by seismic reflection images, suggesting that the ophiolite may not be rooted in Tethyan oceanic lithosphere. We also show evidence for the presence of oceanic crust in the Gulf of Oman, underlying a thick layer of Cenozoic sediments. Our crustal thickness model, derived using the VDSS method, is consistent with the presence of a significant crustal root beneath the mountains. Folding and thrusting due to emplacement of the Semail ophiolite has possibly thickened the Arabian continental crust by 16 km. We propose that the thick crustal keel beneath the ophiolite is folded and thrustured granulite facies lower crust metamorphic rocks, similar to those seen in the Bani Hamid thrust sheet.

Acknowledgments

S.P. acknowledges support from the Natural Environmental Research Council (NERC) Grant NE/R013500/1 and from the European Union's Horizon 2020 research and innovation program under Marie Skłodowska-Curie Grant Agreement 790203. Data acquisition in the UAE was supported by The Petroleum Institute Research Centre Project LTR14011. We are grateful to WesternGeco for providing the time-migrated reflection line and performing depth-migration processing on our reflection profiles. We thank Brook Keats and Tyler Ambrose for insightful discussions about the tectonics of the Semail ophiolite. The dataset used in this study is from Pilia et al. (2020a). For the review process we provide the raw dataset for both active and passive seismic at the following online repository (<https://figshare.com/s/74748023b4382db32457>).
