Key points:

1. Previously unknown faults that belong to the North Anatolian Fault system have been discovered in Lake Iznik through geophysical surveys (from multibeam bathymetry and high-frequency seismic reflection data).

2. Assessment of the recent activity of the Iznik Fault, based on multiproxy analysis of sediment cores from each side of the fault.

3. Evidence for the timing of the last rupture corresponding to the 1065 CE historical earthquake, which had significantly impacted the city of Iznik.

Abstract

The seismic activity of the middle strand of the North Anatolian Fault (MNAF), Northwestern Turkey, is debated because of its quiescence during the instrumental period, in contrast to a significant historical activity documented by several chronicles over the last two millennia. Here, we focus on Lake Iznik, bordered by the MNAF, to get a new insight into its long-term seismicity and its tectonic setting. The study of lacustrine sediment cores reveals fourteen earthquake-induced turbidite deposits since their ages correspond to seismic events during the past two millennia. Bathymetry and high-resolution seismic reflection data allow to describe two hitherto unknown subaquatic active fault structures (the Boyalica and Iznik faults) that belong to the MNAF system. Sediment cores sampled on both sides of the Iznik Fault document an event deposit and a sedimentary unit vertically offset of ~50 cm interpreted as the last rupture during the 1065 CE destructive earthquake. Older events are supposed on this fault more than thousand years ago. Further studies will help to estimate the horizontal coseismic offset of this oblique-slip fault and the calendar of older ruptures. The current seismic gap of thousand years on this segment greatly increases the seismic hazard in this region and must be considered in the seismic risk assessment of the NAF system.

Plain Language Summary

During large earthquakes, sediments are generally transported from lake slopes to the lake basin. The resulting event deposits can provide information on the recurrence of past regional earthquakes, which is crucial for seismic hazard assessment. In this study, we discovered two underwater fault structures in Lake Iznik, using geophysical methods. Studying the sedimentation on both sides of the southernmost fault, we observed an increased sedimentation rate on the hanging wall of the fault immediately after an event deposit, dated at 1096 +/- 86 cal. CE. We interpreted these indicators as resulting from a coseismic vertical displacement along the fault plane, corresponding to the 1065 CE earthquake, which had significantly impacted the city of Iznik. We also show that most of the other event deposits in the sediment cores are confidently associated to 14 historical earthquakes.

Keywords: North Anatolian Fault, Lake sediment, Fault activity, Earthquake, Turbidite, paleo-seismicity.

53   **1. Introduction**

54   Earthquakes are the costliest and deadliest natural events in Turkey with about 100,000 deaths in the last

55   century (Öcal, 2019). Despite their lower frequency compared to other events such as floods, the impact of

56   earthquakes cannot be ignored in this densely populated part of the world. The seismic hazard in the

57   northwestern part of Turkey is mainly linked to the North Anatolian Fault (NAF), a 1500 km-long right-

58   lateral strike-slip fault, which accommodates the westward migration of the Anatolian microplate, away

59   from the Eurasian/Arabian collision (Reilinger et al., 2006).

60   In its western termination, the NAF zone displays a complex organization as it is divided into three

61   branches (*Fig.* 1). Its northern strand (NNAF) continues south of Istanbul through the Marmara Sea (e.g.

62   Armijo et al., 2005). Its middle strand (MNAF) borders the south of two successive basins, known as the

63   Geyve-Pamukova Basin and the Iznik Basin, which hosts Lake Iznik and continues through the Gemlik

64   Bay to the southern shore of the Marmara Sea (*Fig.* 1). Its southern strand (SNAF) is less pronounced in the

65   landscape and extends across the Bursa Province (*Fig.* 1). With a relative horizontal motion estimated

66   around 5 mm/yr by GPS (Ergintav et al., 2014), both MNAF and SNAF show a deformation rate 5-fold

67   smaller than the NNAF (~ 25 mm/yr) (Reilinger et al., 2006). This is also reflected by the recent seismicity

68   of the NAF: from 1939 to 1999, a sequence of great earthquakes (moment magnitude Mw > 6.8) shifted

69   westward from Erzincan to Düzce and Izmit (*Fig.* 1; Stein et al., 1997). The last major earthquake on the

70   NNAF occurred in 1999 along the Izmit-Sapanca rupture and was a 7.6 Mw event. A ground-motion study

71   revealed that this fault segment broke with a supershear velocity during the earthquake (Bouchon, 2002).

72   This destructive event caused extensive liquefaction-induced ground deformation on the shores of Lake

73   Sapanca triggering the submergence of a hotel (Cetin et al., 2002). The succession of the earthquakes on

74   the NNAF is explained by the cumulative Coulomb stress along the fault (Stein et al., 1997). According to

75   this concept, a seismic gap is inferred on the NNAF segment in the Marmara Sea, which was seismically

76   inactive since the 18th century (Hubert-Ferrari et al., 2000). This future rupture may lead to a Mw > 7

77   earthquake and strike Istanbul (Parsons, 2000; Armijo et al., 2005). However, these different models only

78   encompass the recent seismicity (since 1700 CE) on the NNAF branch, but do not take into account either

79   the MNAF or the SNAF. While the SNAF produced a 7.3 Mw earthquake in 1953 and a 6.9 Mw

80   earthquake in 1964 (Ambraseys, 2002), no major earthquake ruptured on the MNAF for several centuries,

81   and a very low seismicity has been recorded during the instrumental period. These observations have led to

82 the assumption that this branch possibly became deactivated (Le Pichon et al., 2014). The last big

83 earthquake on the MNAF may have occurred between the 14th and 18th centuries CE (Ambraseys, 2002).

84 This long quiescence strongly contrasts with a significant historical tectonic activity on the MNAF. Several

85 chronicles and archaeological studies report the partial destruction of Iznik (previously called Nicaea) and

86 surrounding cities following ~ 15 major earthquakes within the last 2000 years, without any precision on

87 the rupture segments (Ambraseys & Finkel, 1991; Ambraseys & Jackson, 2000; Ambraseys, 2002;

88 Benjelloun, 2017). The quiescence of the MNAF in recent times may hide a longer seismic recurrence,

89 which possibly is just as hazardous as the NNAF (according to their span of quiescence), but has been

90 underestimated by the models. This study aims to precise the calendar of seismicity on the area of Iznik and

91 to provide new data for the tectonic setting of the MNAF to precise the seismic cycle of this fault strand.

92 Lake sediments are continuous archives used to reconstruct past earthquake history (Monecke et al., 2004;

93 Strasser et al., 2006; Christian Beck, 2009; Strasser et al., 2013; Van Daele et al., 2015; Avşar et al., 2015;

94 Wilhelm et al., 2016; Moernaut et al., 2017; Rapuc et al., 2018). Compared to historical and terrestrial

95 archives, lake sediments provide a complementary and more continuous paleoseismic record (e.g. Strasser

96 et al., 2013; Wilhelm et al., 2016). Combining on-fault studies such as trenching with studies investigating

97 earthquake-induced turbidites in lakes not only provide direct evidence for fault displacement in the case of

98 surface ruptures, but also allows to document seismic events off-fault without surface ruptures (Brocard et

99 al., 2016). We propose here to investigate Lake Iznik associating geophysical and sedimentological

100 approach to provide new insights into the seismicity of the Iznik region over the past millennia. These

101 methods have been already used on submarine ocean-floor faults such as in the Marmara Sea or in the

102 Lesser Antilles (Armijo et al., 2005; Beck et al., 2012).

103

111 *(2001). Active faults are shown in red (Benjelloun, 2017; Emre et al., 2018).*

112 **2. Context**

113 ## 2.1 Geological settings and previous studies on the MNAF

114 The NAF was initiated some 11-13 Ma ago within a wider pre-existing shear zone, which became
115 progressively narrower through time (Şengör et al., 2014). While most of NAF segments show right-lateral
116 kinematics, the MNAF and the SNAF show oblique (transtensional) kinematics, with local deformation
117 partitioning between right-lateral strike-slip and extensional regimes (Doğan et al., 2015; *Fig. 2*). The
118 origin of the Iznik Basin is still under debate: it has been interpreted as a superimposed basin evolved due
119 to the intersection of the younger NAF and the Thrace Eskişehir Fault (Yaltırak, 2002; Öztürk et al., 2009)
120 or as a more complex transtensional basin due to MNAF activity (Doğan et al., 2015). The geological
121 inheritance is reflected by the relatively high lithological heterogeneity and tectonic complexity within the
122 watershed (*Fig. 2a*). The Gürle Fault (a segment of the MNAF) is known to have an normal component
123 (Doğan et al., 2015), which explains the current location of the deepest depocentre of Lake Iznik (~ 75 m
124 depth b.l.l.; *Fig. 2a*). This normal component is also expressed by the 100 m-high triangular facets on Lake
125 Iznik's southern shore (*Fig. 2b*). Fault partitioning certainly exists; whereas the onshore Gürle Fault
126 accommodates most of the normal component, another fault segment should somewhere accommodate the
127 dextral component.

128 At least fifteen destructive earthquakes were recorded in historic chronicles during the last two millennia
129 (Ambraseys & Finkel, 1991; Ambraseys & Jackson, 2000; Ambraseys, 2002; Benjelloun, 2017). More than
130 20 trenches carried out on different faults of the MNAF confirmed the fault activity (e.g. Honkura &
131 Işikara, 1991; Barka, 1993; Uçarkuş, 2002; Doğan, 2010; Özalp et al., 2013; see *Fig. 2a* for their locations),

132 but very few of them gave reliable age. It is therefore difficult to conclude on the precise ages of rupture

133 on the different segments of the MNAF, and on their earthquake recurrence rate. The city of Iznik hosts

134 many archeological remains affected by past earthquake occurrences, such as the recently discovered

135 submerged basilica in Lake Iznik (Şahin, 2014; Şahin & Fairchild, 2018). Through a systematic survey of

136 Earthquake Archeological Effects (EAE) on Iznik's buildings, Benjelloun (2017) showed that three damage

137 episodes are recorded: between the 6th and late 8th centuries CE, between the 9th and late 11th centuries CE

138 and after the late 14th century CE. The second episode is clearly related to an earthquake in 1065 CE that

139 was well described in many local chronicles and caused several damages in Iznik, whereas the two other

140 episodes could be explained by different earthquake scenarios.

141 ## 2.2 Lake catchment

142 Lake Iznik (83.5 m a.s.l, 40°26'N, 29°32'E), formerly known as Lake Askania, is located southeast of the

143 Marmara Region (Bursa Province), east of the Gemlik Bay (*Fig*. 1). It is the fifth-largest lake of Turkey,

144 and the largest of the Marmara Region with a N-S and E-W extent of 12 and 32 km, respectively (*Fig*. 2a).

145 The lake has a catchment area of ~1257 km² and a surface area of 313 km². The watershed shows a

146 heterogeneous geology, with a northern part relatively rich in volcanic, metamorphic rocks and carbonates,

147 while the southern part is mostly composed of siliciclastic sediments with only sporadic carbonate and

148 volcanic sections. Iznik has been an important city throughout history. Different archaeological excavations

149 in the area suggest that the first farming activities began 6000-5400 BCE (Roodenberg, 2013). Since the

150 first humans settled in the watershed, the land has been cultivated: cereals, olives, and walnuts were among

151 the most important crops in the Iznik area (Miebach et al., 2016). The lake is peanut-shaped with a non-

152 regular shoreline (*Fig*. 2a). A rough bathymetry of the lake, assembled by the General Directorate of

153 Turkish Hydraulic Works (DSI), shows that the lake comprises three sub-basins, reflecting its tectonic

154 complexity (*Fig*. 2a). One isolated sub-basin is located in the western part of the lake, whereas two sub-

155 basins form the central and eastern parts, with one in the North and one on the South separated by an E-W

156 elongated ridge (*Fig*. 2a). The main inflows are the Sölöz, Nadir, Kuru, Kara and Kiran rivers (*Fig*. 2a).

157 The only outlet of the catchment is the Karsak River, which discharges the waters westward to the

158 Marmara Sea through the Gemlik Bay. The Iznik Basin is bordered by two mountain ranges: the Samanli

159 Mountains (max. elevation 1227 m a.s.l.) to the North, and the Katırli Mountains to the South (1275 m

160 a.s.l.) (*Fig*. 2a). The study of Lake Iznik's sediments have provided an up to 36 kyr-long paleoclimatic

161   archive (Roeser et al., 2012; Ülgen et al., 2012; Viehberg et al., 2012; Miebach et al., 2016). In these past

162   studies of Lake Iznik's sedimentary archives, no event deposits were identified in the sedimentary
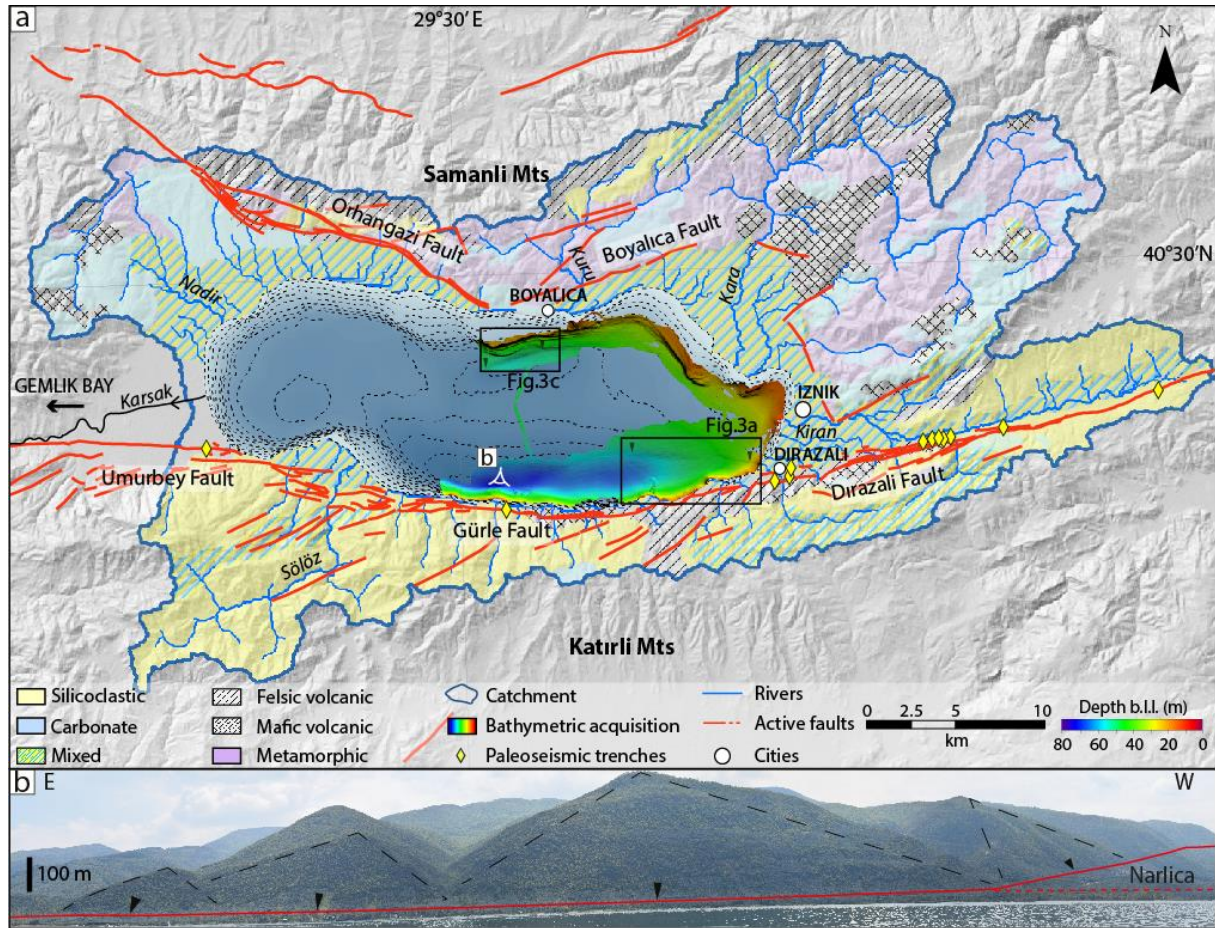

163   sequence.

164

Fig. 2: (a) Lithological map of the watershed of Lake Iznik (modified from Viehberg et al., (2012)) and limits of its catchment (dark blue line). The hillshade relief is generated from the SRTM DEM (1 arc-second resolution). The main rivers are drawn in blue. The MNAF and other active faults are represented in red (Benjelloun, 2017; Emre et al., 2018). The bathymetric contour lines in the lake represent 5-meter intervals (DSI), superimposed by the hillshaded bathymetry acquired in this study (2 m grid), with a sun illumination angle/elevation of 20°N/45° respectively. A vertical exaggeration of 15 was applied. The color scale represents the depth below lake level (b.l.l.), based on a long-term reference lake level of 83.5 m above sea level. The black arrows show the visible extremities of the two newly discovered faults. The black rectangles indicate the location of Fig. 3a and c. (b) Photography of the southern shore of the lake taken from the lake and facing southward, showing triangular facets (black dashed lines) along the Gürle Fault (black arrows). These patterns highlight the significant normal tectonic component in this area.

176 **3. Methodology**

177 ## 3.1 Bathymetry

178 The bathymetric survey was completed in April 2019 using a fishing boat with a Kongsberg EM2040

179 multibeam echosounder (Kongsberg Maritime, Horten, Norway, provided by University of Bern) in a

180 single-head configuration (1° by 1° beam width, 300 kHz standard operating frequency; 400 depth

181 detections per ping). The angular coverage was 148° maximum, with a coverage of up to ~3 times water

182 depth on a flat bottom. The transducers and auxiliary sensors Kongsberg Seatex MRU5+ motion sensor

183 (Kongsberg Seatex, Trondheim, Norway), a Trimble SPS361 heading sensor (Trimble Navigation Limited,

184 Sunnyvale, CA, USA), a Leica GX1230 GNSS receiver (Leica Geosystems, Heerbrugg, Switzerland) using

185 the TUSAGA Aktif GEO real-time positioning service (national active fixed GNSS, Turkey; typical

186 position accuracy 2 to 3 cm) and a Valeport MiniSVS sound velocity sensor (Valeport Limited, Totnes,

187 UK) were used. The transducers, motion sensor and mini sound velocity sensor were incorporated in a

188 rigid mounting attached to the bow of the ship. The ship speed ranged from 7-9 km/h.

189 The vertical sound velocity in the water column was recorded daily by a Valeport Sound Velocity Profiler

190 (SVP) that recorded pressure, temperature and the sound velocity in the water column. Sound velocity

191 depends on the temperature and the salinity of the water. The absolute depth accuracy depends on the

192 correctness of the water velocity profiles, the motion sensor's capability to compensate for ship movements

193 due to waves, positioning accuracy, the water depth and is in the range of centimeters (shallow waters) to a

194 few decimeters (>50 m depth). Data were recorded using Kongsberg's SIS software and processed in

195 HIPS/SIPS 10.4.13 software (University of Bern), then interpreted using ArcGIS 10.4.1.

196 ## 3.2 Seismic acquisition

197 The seismic profiles were acquired using a 3.5 kHz system (Geopulse, Geoacoustic) in 2005 with a single-

198 channel streamer (20-elements AE5000, GeoAcoustics) and an array of four sub-bottom profiling

199 transducers (Mod. TR-1075A, Massa, USA) as receivers. Shot interval was 1 second. For navigation, a 3x4

200 m UWITEC aluminum platform ("R/V Helga") equipped with 4 inflatable tubes for flotation and a 25 HP

201 outboard engine were used. The average speed of the vessel was 5 km/h. All 3.5 kHz data were digitized

202 (Octopus 360, Octopus Marine Systems, UK) and processed (15 to 5000 Hz filtering) using Reflex

203   software (Sandmeier Software, Germany). All profiles were interpreted using IHS Markit® Kingdom

204   v.2015.

3.3 Coring and lithological description

206   Five short cores (registered in the French national cyber-core-repository https://www.cybercarotheque.fr

207   and the open international database www.geosamples.org as IZN19_03 (1.37 m; IGSN: **pending**),

208   IZN19_04 (1.60 m; IGSN: **pending**), IZN19_16 (1.25 m; IGSN: **pending**), IZN19_21 (2.70 m; IGSN:

209   **pending**) and IZN19_31 (2.79 m; IGSN: **pending**)) were collected from Lake Iznik in April and July,

210   2019, using a UWITEC gravity corer with hammering. The cores were sampled on strategic points,

211   depending on the first bathymetric and seismic results. In the laboratory, the cores were split into two

212   halves. Each core was photographed after oxidation and a detailed sedimentological description was

213   performed. The lithological description of the sequences allowed the identification of different sedimentary

214   structures and facies, which were then correlated between the cores. Colors were assigned according the

215   Munsell's color chart (Munsell Color, 1994).

3.4 Sedimentological analysis

217   **Grain-size analysis**

218   The grain-size distribution of the sediment was determined following a mean of 5 cm sampling step all

219   along the longest sequence (IZN19_21; *Fig. 3* for location). As the sequence contains sporadic mm-thick

220   sandy deposits, the resolution in these parts was increased to 0.5 cm. A Beckman Coulter Life Science

221   13 230 XR laser particle-size analyzer was used (EDYTEM Laboratory, University Savoie Mont Blanc)

222   with sonication to avoid particle flocculation. Two runs with a 30s-long measurement were applied for each

223   fresh sample. Results of the grain-size distribution were processed with MATLAB R2016b software and

224   presented in a contour plot with a color-scale according to the abundance of particles in percentage for each

225   grain-size class (*Fig. 5*a).

226   **Scanning Electron Microscopy (SEM) and Energy-Dispersive Spectroscopy (EDS)**

227   To complete the core description, a representative 8 cm-long slab including two coarser-grained deposits

228   was resin-embedded to make 1 mm-thick thin sections of the sediment, which were analyzed with a Vega3

229   Tescan Scanning Electron Microscope (ISTerre Laboratory, University Grenoble Alpes) following

230   covering with a graphite layer of 20 μm. Representative areas of the thin section were additionally analyzed

231   with an Energy-Dispersive Spectroscopy (EDS) probe (Rayspec with SamX's electronic system and

232   software, ISTerre Laboratory) to examine the elementary composition and to map chemical elements on

233   specific lamina.

234   **Loss on ignition**

235   The loss on ignition (LOI) analysis was performed on the IZN19_31 sequence (*Fig. 3* for location), with a

236   10-cm sampling interval all along the sequence to estimate organic matter (OM) and carbonate proportion

237   in the sediment, following the protocol described by Heiri et al., (2001).

238   ## 3.5 Geochemistry

239   The relative contents of major and trace elements were analyzed with an X-Ray Fluorescence (XRF) at 1-

240   mm resolution on the surface of each sediment core with an Avaatech Core Scanner (EDYTEM

241   Laboratory). The split core surface was first covered with a 4-μm-thick Ultralene film to avoid

242   contamination and desiccation of the sediment. Element intensities are expressed in counts per second

243   (cps). Different settings were used with 10 kV and 0.2 mA during 15 s to detect Al, Si, S, K, Ca, Ti. and at

244   30 kV and 0.3 mA during 20 s for Mn, Fe, Ni, Cu, Zn, Br, Rb, Sr, Zr, Pb (Richter et al., 2006). A Principal

245   Component Analysis (PCA) was performed on the geochemical results using R software version 3.5.1 (R

246   Core Team, 2018) to determine correlations between the different measured elements and to identify

247   principal sediment end-members, which are used to better constrain each sedimentological facies (e.g.

248   Sabatier et al., 2010).

249   ## 3.6 Chronology of the cores

250   Eleven ^{14}C analyses of eleven organic plant macro remains were performed by accelerator mass

251   spectrometer (AMS) at the Poznan Radiocarbon Laboratory. The ^{14}C ages were calibrated using the

252   Intcal13 calibration curve (Reimer et al., 2013). Calibrated ages are expressed in the Common Era (CE)

253   timescale: years before the CE are denoted BCE (Table 1). The age model and the sedimentation rate were

254   calculated using the R code package *clam* (Blaauw, 2010). The best fit was obtained by applying a smooth

255   spline model with 0.44 for the smooth parameter.

256 **4. Results**

257 ## 4.1 Lake Bathymetry

258 One third of the surface area of Lake Iznik (~ 80.5 km²), was mapped in high-resolution (*Fig.* 2a). Two

259 prominent lineaments were discovered on the bathymetric data. One is located to the north, parallel to the

260 onshore Boyalıca Fault and strikes NE-SW. This lineament separate the northern sub-basin and the

261 shoreward underwater terraces (*Fig. 3*c).

262 The other lineament, striking NW-SE, has been discovered on the southeastern part and mapped over a

263 distance of 9 km (*Fig.* 3a). It separates the southern sub-basin from the central ridge (*Fig. 2*) in the middle

264 of the lake. This lineament presents two kinks separating it into three segments: IFS1, IFS2 and IFS3 (*Fig.*

265 3a*). IFS1 and IFS3 are ~3 km length (*Fig.* 3a). The bathymetric profile perpendicular to the IFS1 shows a

266 ~1 m vertical offset of the lake floor (profile P1; *Fig.* 3d), extending over a distance of ~100 m. These

267 segments are linked by IFS2 whose scarp is barely visible on the bathymetric data (*Fig.* 3a). Furthermore,

268 numerous pockmarks are visible along the fault trace at the transition from IFS2 to IFS3, indicating fluid

269 escapes (*Fig.* 3b). The size of these depressions varies from few centimeters to 6 m diameter and reaches

270 ~60 cm deep (*Fig.* 3d). If the lineament extends ashore, it merges into the main branch of the MNAF, close

271 to the village of Dırazali. However, the surface expression of the fault is masked by human activity, mainly

272 due to fields of olive and fruit trees. According to these observations, we interpreted this lineament as a

273 fault, termed Iznik Fault.

274 ## 4.2 Seismic reflection data

275 High-resolution seismic profiles were acquired across IFS2 and IFS3 (*Fig. 3*a). These single-channel

276 reflection sections show maximum acoustic penetration of ~10 ms two-way travel time or ~7.5 m

277 (assuming acoustic velocities of 1500 m/s), after which signals become weaker and difficult to interpret due

278 to high gas content of the sediment. A mass-movement deposit indicating a slope failure at the location of

279 IFS3 is visible on the seismic section (Profile P2; *Fig. 4*) supporting the fault nature of the lineament and its

280 location. Although it is difficult to assess vertical offset on the different seismic profiles, the continuity of

281 the seismic reflections is affected across the fault. The second seismic section parallel to IFS2 (Profile P3;

282 *Fig. 4*), does not show any clear slope failure but only slight vertical offsets of the seismic reflections and a

283 series of closely-spaced incipient faults displacing steeply the uppermost meters of sediment.

284

285

Fig. 3: (a) Hillshaded bathymetric map (5 m grid) of the southeastern part of the lake (Fig. 2 for location).

A vertical exaggeration (ve = 20) is applied to highlight the Iznik Fault trace. The black arrows denote the

extremities of the different visible segments of the Iznik Fault, termed as IFS1, IFS2 and IFS3 from east to

west. White dots represent the core locations (IZN19_03, 04, 31, 21, 16). Black lines indicate topographic

P1 (Fig. 3d) and seismic section locations (P2 and P3; Fig. 4). Subaerial elevation is derived from the

SRTM model (1 arc-second resolution). The bathymetric and topographic scales are relative to the lake

292 *level, below and above (denoted as b.l.l. and a.l.l, respectively). Active faults ashore are shown in red*

293 *(Benjelloun, 2017; Emre et al., 2018). Inset is an overlay of hillshade and slope maps to emphasize the*

294 *fault traces. Black arrows indicated the termination of IFS1 and IFS3. In the lower part, an interpretative*

295 *sketch of the fault geometry is shown. (b) Zoom of the pockmarks along the fault, indicating fluid escapes*

4.3 Sedimentary sequences

Sedimentary facies

Lake Iznik sediments consist mainly of clayey to silty grained (Roeser et al., 2012; *Fig.* 5). In the here

investigated short cores, very fine to fine sand layers appear very sporadically at the millimeter scale in the

finer matrix of background deposits. Based on macroscopic observations and confirmed by geochemical

311   analysis, four main lithologic facies were identified. Facies Ia is composed of brown (5Y/4/4) silty-clay

312   (D50 = 10 μm) and occurs at the top of each core. The organic proportion (LOI550) of this facies amounts

313   to ~9 % and the carbonate proportion (LOI950) to 6 %. Facies Ib occurs at different depths in the sequences

314   and consists of slightly coarser light brown (2.5Y/5/4) silt (D50 = 15 μm). Facies Ib has the highest

315   proportion of organic matter (~10 %) and carbonate (~10 %). The majority of the sedimentary sequence

316   consists of Facies II, which is a more heterogeneous facies with olive grey color (5Y/6/2) clay (D50 = 8

317   μm). This facies is interrupted by a total of 15 and 18 few-mm-thick (max 2 cm-thick) sandy layers in cores

318   IZN19_31 and IZN19_21, respectively, denoted as Facies III and termed 'event layers' (D50 = 20 μm). This

319   facies shows the lowest proportion in organic matter (~7 %) and carbonates (~7 %). Nevertheless, LOI

320   values do not vary much over the entire sequence. The fraction of non-carbonate ignition residue (NCIR) is

321   higher than 80 % for the whole sequence (*Fig.* 5a). All event layers appear to the naked eye as mm-thick

322   levels of very fine silt/sand or silty lenses within the continuous sedimentation of Facies II. The detailed

323   SEM observations show that these sandy layers have an erosive base incising into clayey sediments and a

324   fining-upward trend. Bioturbation with vertical burrows is present throughout their base. Burrow length

325   varies from 1 to 4 mm, and they are filled with particles to the overlying layer (*Fig.* 5c). Moreover, a

326   comparison of the oxide composition of two event deposits compared to the background sedimentation has

327   been performed with the EDS sensor (*Fig. 5*c). These maps show that Facies II and III have the same major

328   element compositions and that all carbonates within the Facies III are mostly composed by Ca and Mg and

329   reach 50 μm (*Fig.* 5c). Facies III layers are distinct from Facies II due to their fining-upward trends, their

330   erosive base and the coarse-grained Ca/Mg-carbonates (*Fig.* 5).
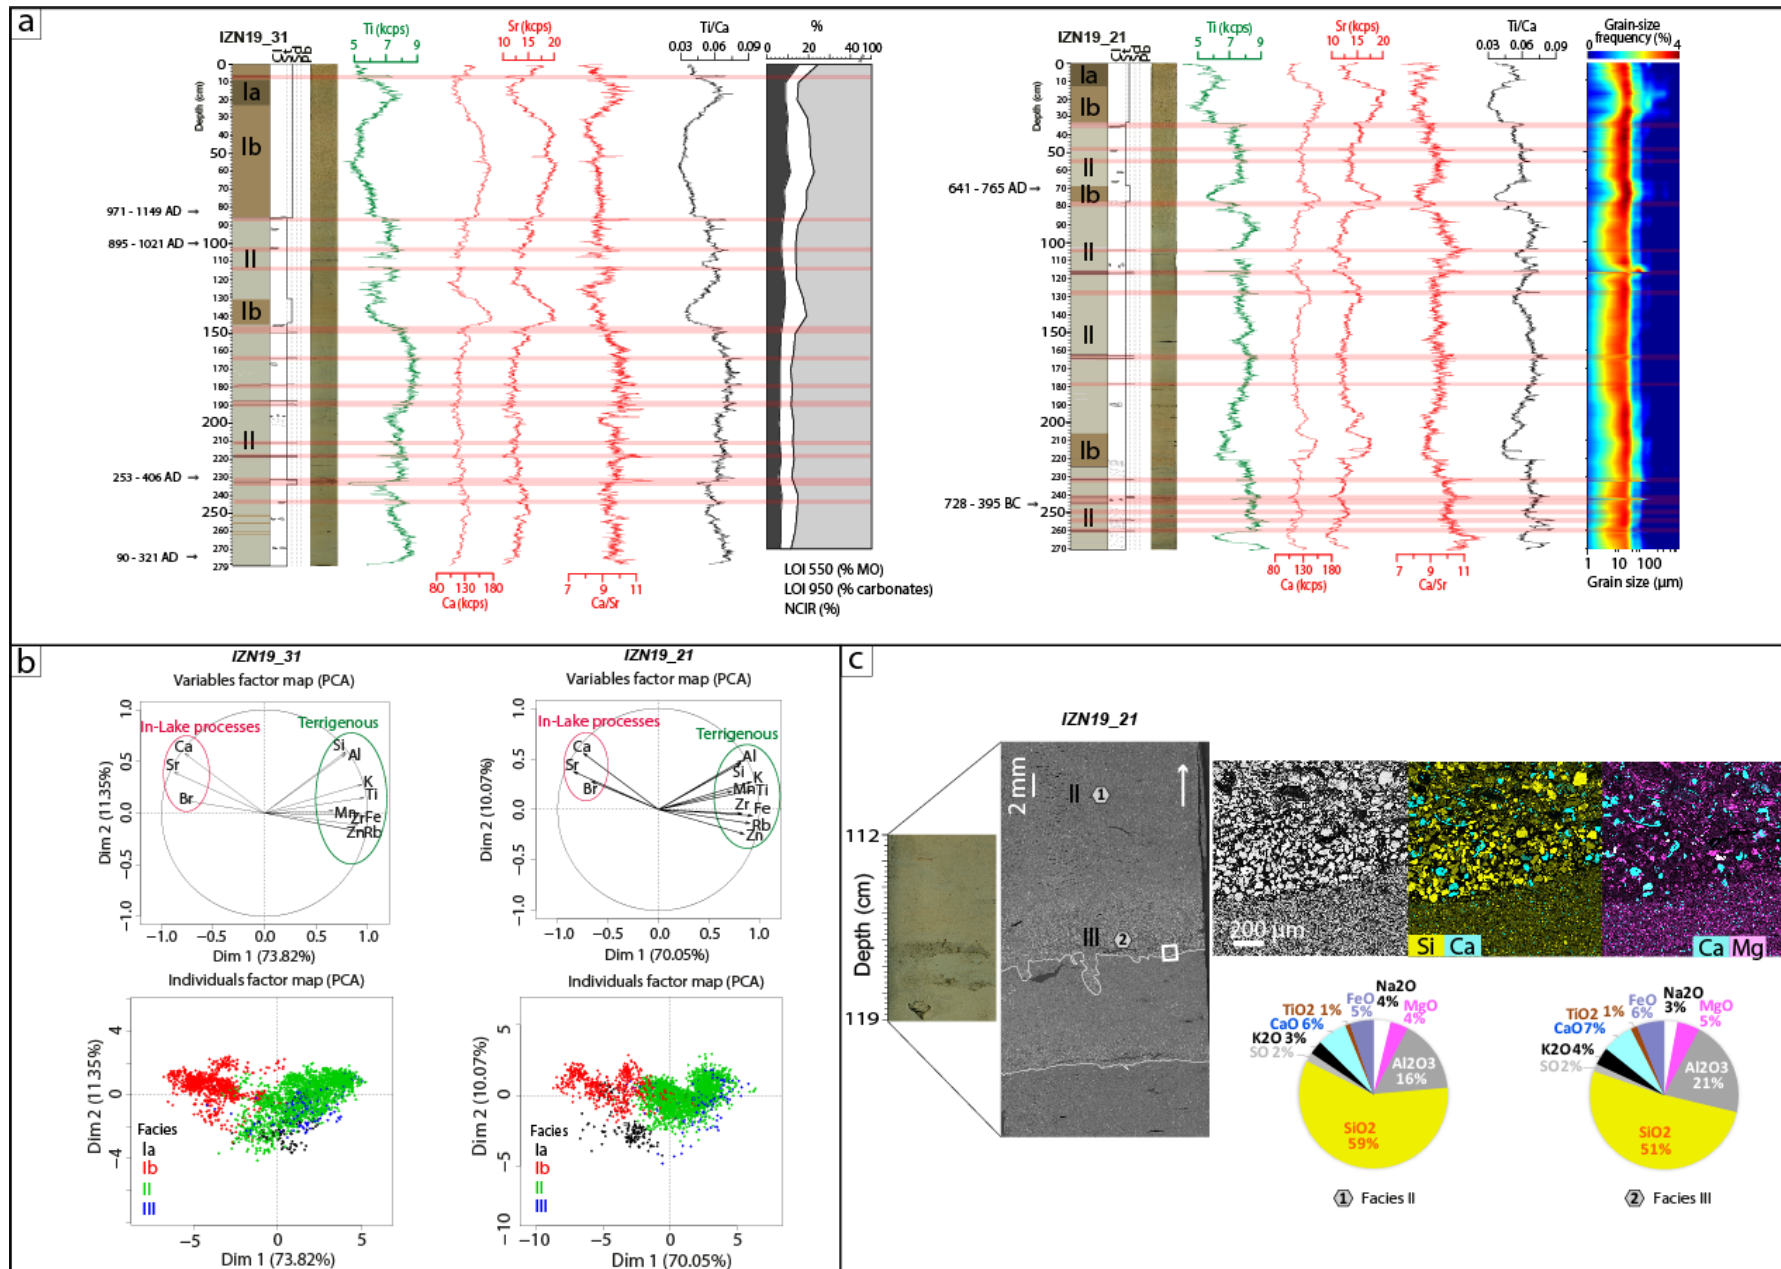

331   **Geochemistry**

332   PCA was conducted on the XRF geochemical data of both IZN19_31 and IZN19_21 cores located on both

333   sides of the fault (*Fig.* 5b). Dimensions 1 and 2 (denoted as Dim 1 and Dim 2) explain 85.17% and 80.12%

334   of the total variability for IZN19_31 and IZN19_21 cores, respectively. From the variables factor map, two

335   end-members could be identified. The first one, denoted as "terrigenous", shows high positive loadings

336   with Dim 1 (e.g. Al, Si, Ti, K, Rb; in green in *Fig.* 5a and b). The second end-member is interpreted as "in-

337   lake processes" (Ca, Sr, Br). It displays negative loadings on Dim 1 and positive loadings on Dim 2 (red in

338   *Fig.* 5a and b). We link it to the endogenic carbonate production and organic matter (Guevara et al., 2019).

339   The individual factor map highlights the characteristics of each facies. Facies Ib is dominated by the

340   endogenic process end-member, and it is also characterized by high Ca, Sr and Br counts (*Fig.* 5b). In

341   contrast, Facies II is influenced by terrigenous input. Facies Ia is in an intermediate position with relatively

342   higher Ti counts than Facies Ib (*Fig.* 5a). Facies III shows a similar geochemical characteristic as Facies II

343   (*Fig.* 5c).

344   **Core-to-core correlation**

345   On the basis of the lithological description and XRF measurements, a correlation between the cores across

346   the Iznik Fault is proposed (*Fig. 3*a and *Fig. 6*). The IZN19_03 Core has been excluded from the

347   comparison to limit uncertainties because of its distance to this transect (IZN19_03 Core is presented

348   Figure S1 in the supporting information). On *Fig. 6*, the Dim 1 (terrigenous supply vs. in-lake processes)

349   and the Ca signal are displayed to highlight the stratigraphic units correlation. Five different stratigraphic

350   units (from top to bottom: purple, green, orange, dark blue, grey) were correlated on the P1 profile across

351   IFS1 (*Fig. 3*d). Thickness of these units varies significantly, particularly between cores in the immediate

352   vicinity of the fault, IZN19_31 on the hanging wall and IZN19_21 on the footwall of the fault. Based on

353   the stratigraphic correlation, it was possible to correlate the radiocarbon dates (*Table 1*) to IZN19_21 and

354   IZN19_31 cores and use all of them for age modeling.

355

356   *Fig. 5 (next page): Main sedimentological and geochemical results of IZN19_31 and IZN19_21 cores. (a)*

The different colors represent five stratigraphic units. Event deposits are shown in red. Individual radiocarbon dates are shown with black arrows (Table 1 for details). Ia, Ib, II represent the names of the different facies types defined in the text.

4.4 Radiocarbon dating and age models

Eleven organic terrestrial plant macroremains were dated (*Table 1*) and stratigraphically correlated between cores IZN19_31 and IZN19_21. This allowed us to use all dates on both cores for age modeling (*Fig. 7*). Both cores have almost the same length (279 cm and 270 cm, respectively) and they were taken very close one to the other (200 m apart) on each side of the fault. The core located north of the fault (IZN19_21) spans a larger period of time and reach at the base 625 cal. BCE, whereas the core south of the fault (IZN19_31) encompasses a shorter time period with the base reaching ~170 cal. CE. These different basal ages clearly document the higher sedimentation rates south of the faults. Core IZN19_31 shows more pronounced variations in the sedimentation rate, and four periods can be differentiated (*Fig. 7*). (1) a period with a relatively high sedimentation rate from 175 to 400 cal. CE. During this period, the sedimentation rate is almost constant (~2.4 mm/yr); (2) The sedimentation rate show a significant increase from 400 to 600 cal. CE reaching 4.7 mm/yr; (3) The sedimentation rate decrease and become stabilized at 0.8 mm/yr around 1200 cal. CE; and (4) Sedimentation rate increases from 1200 cal. CE until the modern period (1.2

388   mm/yr at the top). Core IZN19_21 shows the same trends but with less pronounced variations lacking also

389   the most recent increase in recent times (*Fig. 7*).

390

Sample name	Core	MCD (cm)	Radiocarbon age (yr BP)	Age cal BCE/CE 2σ range	Sample type
IZN19_20	IZN19_03	68	1170 +/- 35	770 – 969 CE	Plant remains

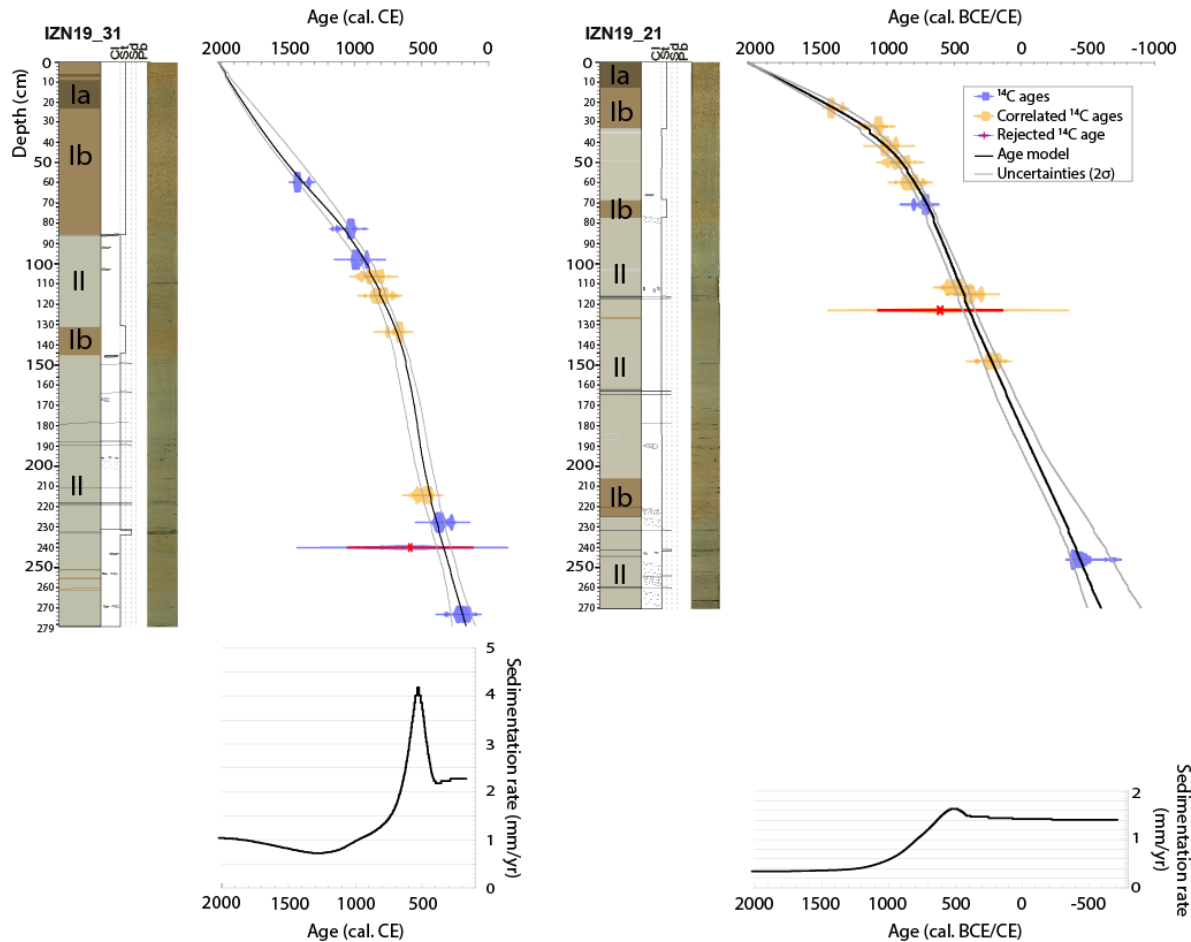

Fig. 7: Lithological description, photography, age model for cores IZN19_31 and IZN19_21 and their respective sedimentation rate variation curve through time. The age models are computed with Clam R package (Blaauw, 2010) *using the radiocarbon data (Table 1). The blue dates origin in the displayed core itself; the orange radiocarbon ages are those which are correlated from other sequences (Fig. 6). One radiocarbon age has been rejected for the age model computation due to its large uncertainty (marked in red, details in Table 1).*

5. Discussion

5.1 Event deposits versus seismic historical archives

The LOI analysis of the cores shows that almost 80% of the whole sediment sequences are composed of terrigenous siliciclastic constituents (*Fig. 5*a), whereas the in-lake carbonate production represents only a minor fraction. Roeser et al., (2016) showed that endogenic calcium carbonates precipitated as aragonite and low-Mg calcite in the lake water column. The terrigenous component is expressed in a high Ti counts,

406 which is characteristic of siliciclastic and felsic volcanic rocks in this part of the catchment (*Fig.* 2a; *Fig.*

407 *5*a, b). Our study reveals evidence for multiple thin Ti-rich sandy normally graded beds termed event layers

408 within Facies II (*Fig. 5*). These deposits show Ca and Sr negative counts excursions suggesting a decrease

409 in the proportion of endogenic carbonates (*Fig.* 5a, b). They are interpreted as turbidites because of: (1) the

410 macroscopic lithological and structural description; (2) their higher proportion in terrigenous elements as

411 indicated by the Ti/Ca ratio (*Fig.* 5a) and (3) their higher values of detrital carbonates shown by the Ca/Sr

412 ratio and the presence of Ca/Mg coarse-grained carbonates (*Fig.* 5a, c).

413 Turbidites can be triggered by several processes such as hyperpycnal flow related to river flooding (e.g.

414 Wilhelm et al., 2015), remobilization of superficial lacustrine slope sediments that have been transported

415 and deposited by turbidity currents (e.g. Hage et al., 2017), in relation to seismically induced massive

416 subaquatic failures of lateral slopes (e.g. Schnellmann et al., 2005) or spontaneous slope failure due to high

417 surcharge in sediments of submerged delta slopes (e.g. Girardclos et al., 2007; Hilbe & Anselmetti, 2014).

418 The last two are less probable as shown by the small slope in this area (less than 5°) (Schnellmann et al.,

419 2005). Turbidite deposits are getting thinner from SW to NE (*Fig.* 6) and some of these deposits are absent

420 in Core IZN19_16, which is farther away from the closest significantly sediment contributing delta (*Fig.*

421 3a). The frequency of these turbidites and in particular the fact that no deposit has been observed over the

422 last 1000 years is difficult to explain with the "flood hypothesis". However, given the active tectonic

423 context of the region, it is plausible that such turbidites are related to shallow slope destabilizations by

424 recurrent earthquakes, as previously proposed for thin turbidites in a similar context of Lake Hazar (~ 900

425 km southeastward; Hage et al., 2017; Hubert-Ferrari et al., 2020). To evaluate this potential seismic cause,

426 the age of the turbidites, deduced from age models of cores IZN19_21 and IZN19_31 are compared with

427 those of the historical earthquakes (Ambraseys & Finkel, 1991; Ambraseys & Jackson, 2000; Ambraseys,

428 2002; Guidoboni et al., 2005; Ambraseys, 2009; Table S1 in supporting information). The sensitivity of

429 Lake Iznik to record regional earthquakes can be characterized by the Earthquake-Sensitivity Threshold

430 Index (ESTI) (Wilhelm et al., 2016), for which the sedimentation rate is critical in controlling the ability of

431 a lake system to record earthquake-induced deposits: the higher the sedimentation rate is, the greater the

432 ESTI and the more likely it is to record earthquakes. As the sedimentation rate changes through time (*Fig.*

433 7), the ESTI of Lake Iznik also changed accordingly. A weighting of earthquake magnitudes by the

434   sedimentation rate over 100 years prior to the event is performed, thus the relationship between the

435   sedimentation rate and the turbidites occurrence is explored in *Fig. 8*.

436   In Core IZN19_21 that spans a longer time period till 625 cal BCE, eighteen distinct event deposits are

437   observed. Six of them are older than 0 cal CE; thus predate the first historical seismicity records for this

438   area. For the twelve remaining sandy layers, eleven historical earthquakes can be related to turbidite

439   deposits (*Fig. 8*e, f). The last event layer is identified in the higher sedimentation rate period (450 to 600

440   cal CE) probably related to enhanced erosion by intense human activities during Roman time (Arnaud et

441   al., 2016; Bajard et al., 2017) such as agriculture as reflected in high amounts of olive-tree pollens

442   (Miebach et al., 2016). These fields were abandoned around 650 CE when Pinus pollen increased (Miebach

443   et al., 2016). This rise in the sedimentation rate explains the increased sensitivity of the lake to record

444   ground-shaking (Wilhelm et al., 2016; Rapuc et al., 2018). During such periods, the lake is prone to

445   recorded earthquakes with significantly smaller magnitude, which might not be reported in historical

446   accounts. We cannot exclude that the deposit could also be related to other triggering mechanism such as

447   flood, considering that at least one flood is mentioned in a historical archive for that time period during the

448   reign of Justinian (527-565 CE) (Evans, 2005).

449   In Core IZN19_31, fifteen event deposits are described, all of them in the time span of historical accounts.

450   Eleven are associated with earthquakes. The four others also appear in the high sedimentation rate period

451   during which the lake sensitivity was high. Overall, this approach shows conclusive results as twenty two

452   thin turbidites can be associated with earthquakes in both cores, corresponding to fourteen independent

453   earthquakes (*Fig. 8*). In turn, those historically known earthquakes that were not recorded by a turbidite are

454   generally separated by only few years. As an example, two sandy layers visible in Core IZN19_31 at 232

455   cm depth (*Fig. 5*) are not present in the IZN19_21 sequence. Based on the age model (*Fig. 8*a), these

456   turbidites could correspond to two of the three historical earthquakes known from that time: 358, 362 and

457   368 CE. According to *Fig. 8*c, the 358 and 362 CE earthquakes seem to be the most prone to be recorded in

458   this part of the lake as they are further from the threshold. Hence, the 358 CE earthquake could have been

459   recorded as a thick deposit (2 cm i.e. more than four times thicker than all other sandy layers), then the

460   overlying thinnest coarse-grained layer probably corresponds to the 362 CE earthquake (*Fig. 8*c). The lack

461   of a third layer marking the 368 CE earthquake thus likely indicates that the slopes did not have enough

462   time to replenish the re-mobilizable sediment stock to form a new turbiditic deposit within only a few years

463   after two earlier earthquakes. Nevertheless, historical data (e.g. Guidoboni et al., 1994) indicate that Iznik

464   was mostly destroyed during the earthquake of 368 CE, so that an alternative hypothesis relates the

465   overlying deposit to this earthquake and uncertainties still remain for the assignments of historical events

466   during this period. Furthermore, Iznik was highly damaged or destroyed by local events in 29 CE, 368 CE,

467   740 CE and 1065 CE with earthquake magnitudes estimated between 6.8 and 7.2 (Ambraseys, 2002). These

468   magnitudes were calculated from the spatial distribution of intensities around the maximum intensity zone

469   (Ambraseys, 2002), which in turn were estimated from historical accounts. However, variable population,

470   changes in building vulnerability over time and exaggeration in the historical sources are difficulties

471   affecting these estimations.

472   Considering the historical location and magnitude (Ms = 6.8) of the 1065 CE earthquake, it should not be

473   recorded in our cores, when it is. Therefore, we should reconsider either the epicenter location or its

474   magnitude.

475   Concerning the instrumental period, ~8500 earthquakes (from 1935 to 2020) are plotted (*Fig. 8*c, f). These

476   earthquakes occurred in an area of 200 km around Lake Iznik and with magnitudes (magnitudes types

477   depending on the earthquakes) ranging from 2.5 to 7.6 (USGS catalogue;

478   https://earthquake.usgs.gov/earthquakes/search/). Among these earthquakes, only the 1999 CE event (Izmit,

479   NNAF) is closed to the sensitivity threshold of the lake for the Core IZN19_31, while it is below the

480   detection limit for the Core IZN19_21. On the top of the Core IZN19_31, only one turbidite layer is

481   observed, which could correspond to this earthquake (*Fig. 8*a). The other two earthquakes near the

482   sensitivity threshold (1719 and 1894 CE) actually probably not exceed the sensitivity threshold due to the

483   significant uncertainties on the historical data (precise location and magnitude) (*Fig. 8*c). The strong

484   correlation between historical and instrumental recordings and our sedimentary records supported the

485   reliability of this conceptual approach. These results prove that Lake Iznik's sediments record the past

486   regional seismicity on the different branches of the NAF system. Upcoming studies should take into

487   account sediment cores from different sub-basins of Lake Iznik. It will help to distinguish more accurately

488   the source(s) of such coarser grained deposits, their synchronicity in different independent locations being a

489   strong argument for their seismic trigger (e.g. Van Daele et al., 2015).
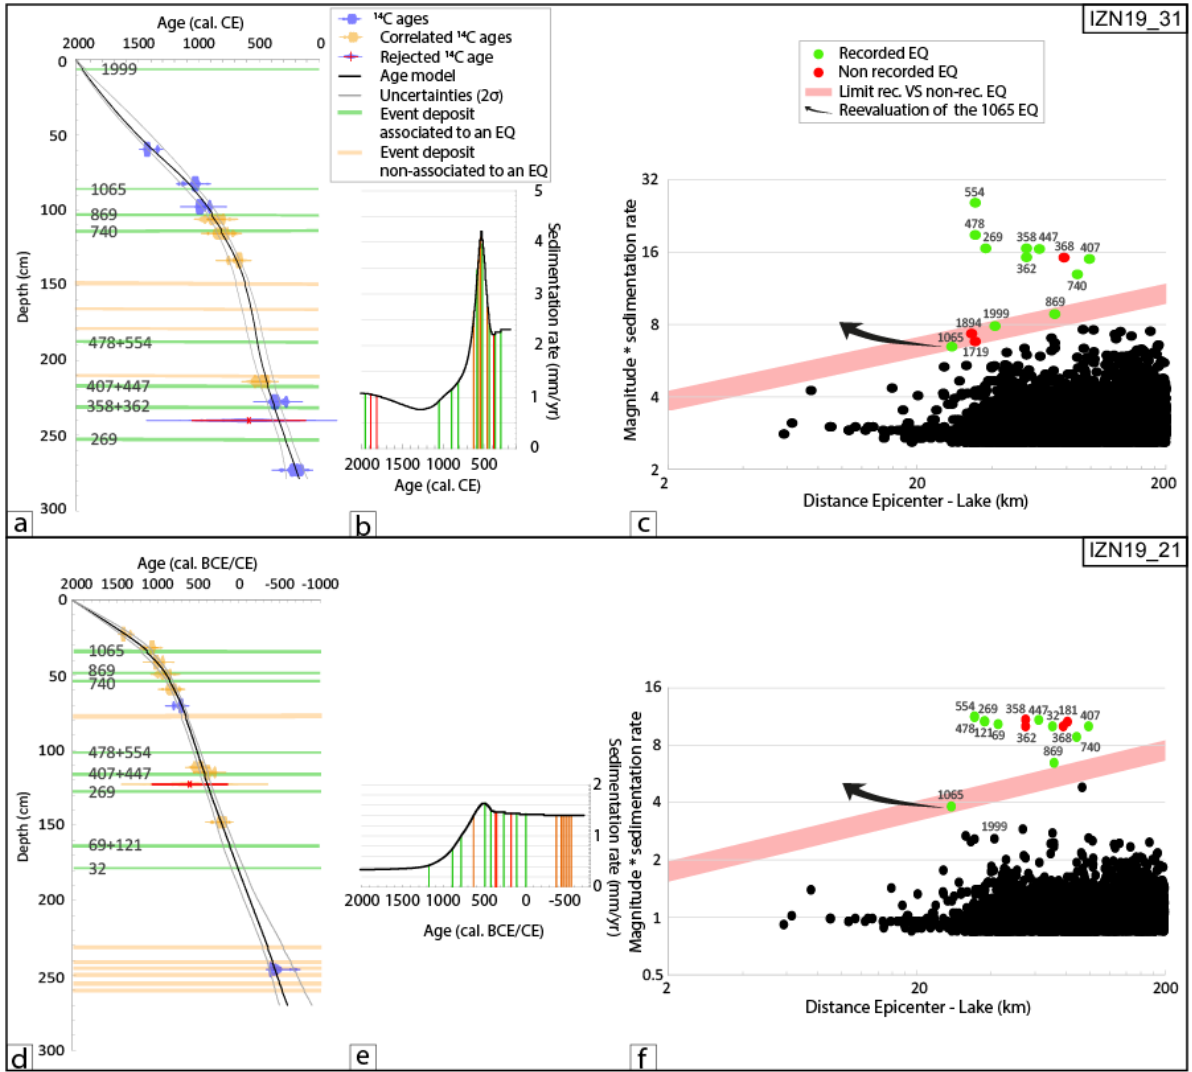

490

Fig. 8: Diagrams displaying for cores IZN19_31 and IZN19_21 (a, d) the interpreted age models. (b, e)

The sedimentation rate variations through time. The green lines represent the event deposits associated to

an earthquake as opposed to the orange lines. Red lines represent times at which earthquakes happened

without event deposit in the sediment cores. (c, f) Conceptual plots presenting the distance of earthquake

epicenters to Lake Iznik (40.406N, 29.673E as reference) versus earthquake magnitudes multiply by the

sedimentation rate averaged over the previous 100 years. The red thick line delimits the best fit versus

recorded and non-recorded earthquakes. Black dots represent earthquakes below the best fit line which are

not recorded in the lake. The black arrows show where the 1065 CE earthquake should be located in the

diagram as the Iznik fault ruptured in the lake at that time (see below in the text).

5.2 Discovery of two hitherto unknown subaquatic faults

500

501 The bathymetric survey carried out in the lake allows to identify two previously unknown underwater faults

502 (*Fig. 2* and *Fig. 3*). The first one is located in the northern sub-basin; striking SW-NE, this fault lineament

503 shows a sharp vertical scarp of ~5 m (*Fig. 3*c), it forming the northward edge of the northern sub-basin and

504 the shoreward underwater terraces (*Fig. 2*a and *Fig. 3*c). This fault segment is parallel and very close to the

505 Boyalıca fault. We consider it is a segment of the Boyalıca fault. The terraces, with depths of 20, 40, and

506 45 m b.l.l. are interpreted as markers of past low lake levels as documented in the Gemlik Bay (Eriş et al.,

507 2019). Based on the lake's shorelines, resembling the shape of a peanut and on general analysis of the entire

508 bathymetric data set (Fig. 2), a left-lateral fault with a small normal component is inferred for the Boyalıca

509 Fault. Microseismic data also document an oblique and normal movement on this fault during a Ms 2

510 earthquake (Gurbuz et al., 2000). Similar SW-NE sinistral faults are observed at the NAF scale, in the

511 Gemlik Bay (Fig. 1) or associated to the NNAF where they comprise antithetic shear components (Alpar &

512 Yaltırak, 2002; Kurtuluş & Canbay, 2007).

513 The second fault discovered in Lake Iznik - termed Iznik Fault - strikes E-W and separates the southern

514 sub-basin from the central ridge (*Fig. 2*). The high-resolution seismic profile across IFS2 shows a series of

515 steep faults interpreted to be arranged en-echelon manner (*Fig. 4, Profile P3*) suggesting that it presents

516 mostly a strike-slip movement. The Iznik Fault seams to cross the entire lake; its eastern prolongation joins

517 the dextral Dırazali Fault onshore and potentially the dextral Gemlik Fault to the west (*Fig. 3*), which

518 would suggest a right-lateral component for this fault.

519 These two subaquatic faults are most likely still active as expressed by the morphological step observed on

520 the lake floor. In particular for the Iznik Fault as indicates by the change in sedimentation rate across the

521 structure and the occurrence of many pock marks indicating fluid escape along the fault, which are favored

522 by deep-seated pathways along the buried fault plane (*Fig. 3b*).

5.3 Identification of the last earthquake rupture on the Iznik Fault

523

524 The core-to-core correlation across the Iznik Fault (IFS1 on *Fig. 3*a) allows to identify thicknesses

525 variations of sedimentary units across the structure. For the present-day profile (*Fig.* 9a), the topography is

526 deduced from the multibeam bathymetry (Profile P1 on *Fig.* 3a). From the sediment-core analysis we

527 retrieved the paleotopography and sedimentological features at different moments by removing layer by

528   layer from the top to the bottom of the cores. For each depth, the age is determined from the age models of

529   cores IZN19_21 and IZN19_31 (*Fig*. 7); the total uncertainty range of the different ages allows to

530   encompass the time span. After removing the pink and green units (*Fig*. 9b), the residual topography is

531   assumed to be the paleo topography at 1010/1182 cal CE. Compaction and erosion are neglected on this

532   reconstruction, as we suppose a similar effect on both sides of the fault as well as similar erosional

533   processes (e.g. deep currents). This reconstruction highlights a sediment thickness variation of ~50 cm

534   between the hanging and the footwall of the fault for the green layer (*Fig*. 9). These thickness variation

535   reflect the fault activity. The co-seismic and vertical offset created an accommodation space on the footwall

536   which then has been gradually filled (*Fig*. 9b). The observation of an event deposit at the base of this green

537   unit also supports this interpretation of fault rupture (*Fig. 8*a). The turbidity current-induced deposit is a co-

538   seismic marker while the sedimentary thickness variation is a syn- to post-seismic indicator; as it has also

539   been observed in the Sea of Marmara along the NNAF (Armijo et al., 2005). This co-seismic event deposit

540   is dated between 1010 to 1182 cal. CE that coincides with the well-documented 1065 CE earthquake

541   (Ambraseys, 2009). The independent archeo-seismological study of Benjelloun, (2017) documents an

542   important phase the destruction-reconstruction for the buildings in Nicaea (formerly Iznik) between 858

543   and 1097 CE. According to the original historical archive (Michael & Attaleiatēs, 2012), the 1065 CE

544   earthquake has strongly damaged the city of Iznik (formerly Nicaea/ Nikaia): "It happened at Nikaia in

545   Bithynia and brought almost total devastation and ruin to the place. Its most important and large churches

546   [...] and the one of the Holy Fathers, where the Council of the most Holy and Orthodox Fathers against

547   Areios confirmed its decisions [...] those churches, then, were shaken and collapsed as did the walls of the

548   city along with many private dwellings.". No other locality seems to have been damaged as strongly as

549   Iznik during this earthquake, which suggests a proximal event rupturing the MNAF. The ~50 cm vertical

550   co-seismic offset could have also triggered a destructive wave (tsunami) or a lake-level variation that led to

551   the destruction and submersion of the basilica of Nicaea (Şahin, 2014), explaining why this basilica has

552   never been rebuilt. The most recent layer (pink in *Fig*. 9a) dated to post 1521/1734 cal. CE shows a

553   thickness increase of ~44 cm in the southernmost shore-proximal Core IZN19_04. Bathymetric data

554   suggest a recent delta-derived clastic contribution to explain this thickness variation. The recent increase of

555   erosion and sediment supply to the lake is likely related to agriculture revival in the catchment (Geyer et

556   al., 2001). The lowermost stratigraphic unit found in our cores, the unit marked in grey, is 62 cm thicker on

557   the southern side of the fault (62 cm vs. <130 cm) (*Fig. 9*c). Such a variation could be also caused by

558   vertical movements of the fault during former earthquakes before the common era, but longer sequences

559   are required to retrieved the base of the grey layer and infer the pre-grey layer topography prior the grey

560   layer to confirm this hypothesis. Further seismic acquisitions could also help to highlight and image

561   stratigraphically deeper units in the hanging wall (e.g. Beck et al., 2012).

570   ## 5.4 Regional implications

571   Linear strike-slip faults such as the Iznik Fault are important tectonic structures as shown by the one

572   discovered within the Lake Sapanca during the Izmit 1999 earthquake, along the NNAF (Polonia et al.,

573   2004). The rupture along this straight segment was of supershear nature and caused strong damages

574   amplified by ground liquefaction (Bouchon, 2002). The presented newly discovered faults provide essential

575   data to better assess the seismic hazard of the region.

576   The description of the whole active fault system in and around Lake Iznik also improves tectonic

577   knowledge. Lake Iznik exhibits three sub-basins that cannot be explained in a simple pull-apart process

578   approach (Wu et al., 2009; Dooley & Schreurs, 2012). The left-lateral Boyalıca Fault presented in this

579   study delimits the western sub-basin from the two others (*Fig. 10*a, b). The Gürle and Orhangazi normal

580   faults bounded the underwater Iznik and Boyalıca strike-slip faults, resulting in a negative flower structure

581   as shown on the simplified NS cross section of the lake (*Fig. 10*c*)*. The basin can thus be divided into three

582   blocks separated by both the left- and right-lateral strike-slip faults document in this study (*Fig. 10*b).

583   Overall, these rather E-W faults show minor vertical displacements suggesting they are mostly strike-slip

584   faults. Similar geometry with basins limited by such faults are observed on models of transtensional pull-

585   apart basins, due to an oblique and divergent displacement at a θ angle with the main strike-slip fault (Wu

586   et al., 2009; Dooley & Schreurs, 2012; *Fig. 10*a). The discovery of the Iznik strike-slip Fault also suggests

587   fault partitioning of the MNAF close to Lake Iznik. The onshore Gürle Fault accommodates mostly the

588   normal component whereas the Iznik Fault seems accommodates most of the right-lateral component of the

589   MNAF system, controlling the shape of the southern sub-basin (*Fig. 10*). In addition to the faults

590   mentioned above that control the sub-basins, other segments lead to the complex configuration of the Iznik

591   Basin. Two extensional structures have been previously studied on the western sub-basin (Öztürk et al.,

592   2009) and to the East of the city of Iznik (the Ebeyli Fault) (Benjelloun et al., 2018). The bathymetric data

593   from the DSI highlights different other scarps that need to be studied more closely (*Fig. 10*a). The

594   combination of all these new observations clarifies that (1) the isolated circular western sub-basin seems to

595   be less deformed and may correspond to a former pull apart, as suggested by its form (2) the formation of

596   the two other elongated sub-basins may be caused by a transtensional motion and (3) the highest central

597   ridge limited by both Boyalıca and Iznik faults is also link to the transtensional movement (Fig. 10b).

598   Given the geological inheritance of this region (e.g. Şengör & Yilmaz, 1981), it is probable that certain

599   fault segments and in particular that of Boyalica, had different components over tectonic phases due to

600   stress field variations during the evolution of the basin, and undergone possible rotations and/or

601   deactivation/reactivation. Further bathymetric and seismic surveys will provide key elements to understand
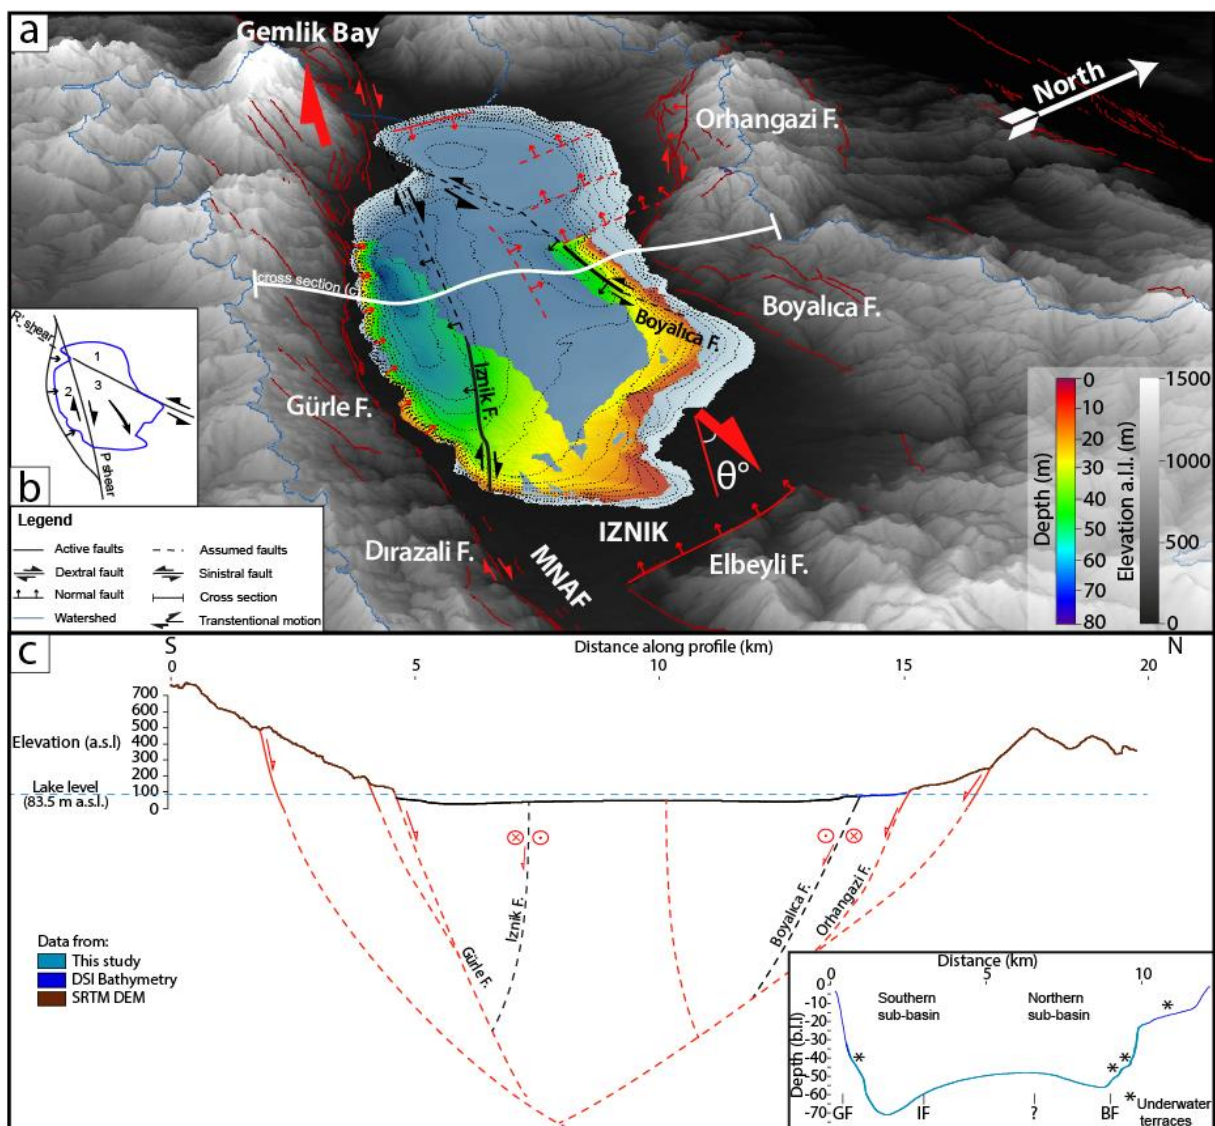

602   the timing of these tectonic controls.

603
604   *Fig. 10: (a) 3D visualization derived from SRTM DEM (1 arc-second resolution) of the Iznik Basin with*

6. Conclusions

613 The sedimentary study done on the cores sampled in the Lake Iznik revealed fourteen earthquake-induced

614 turbidite deposits since their ages correspond to historical regional seismic events during the past two

615 millennia, allowing to refine the calendar of historical seismicity in this region.

616 The combined geophysical and sedimentological approach in Lake Iznik allows to discover two active

617 subaquatic faults: a segment of the Boyalıca Fault and the Iznik Fault that form part of the middle strand of

618 the North Anatolian Fault and that are responsible for some of the recorded earthquakes in the lake. The

619 sedimentological study focused on both part of the Iznik Fault shows paleo-seismological evidences for a

620 last rupture that occurred during the devastating 1065 CE earthquake. Studying longer sequences from the

621 same locations associated to on-fault studies could provide new insights about the earthquake recurrence

622 interval on this specific fault which seems to be longer than 1000 years. The seismic gap since 1065 of this

623 Iznik Fault segment strongly increases the seismic hazard in the region of Iznik and must be taken into

624 account for the seismic risk assessment of the NAF system.

625 Finally, our findings provide a better understanding of the Lake Iznik tectonic context that present negative

626 flower structure due to and important transtensional movement.

635   the excellent services of Captain C. Çelikbilek who maneuvered us on his Vessel safely across the lake.

636   The authors would like to thank EDYTEM laboratory for the X-ray fluorescence analyses and F. Soufi for

637   his involvement in the realization of the thin sections. We also thank N. Findling for his precious help

638   during the SEM observation sessions at ISTerre laboratory and I. Akalan Gündüz for our discussions

639   dealing with the historical data and her help on the field.

Data availability

641   Supplementary data reported in this study are given in the supporting informations and all core and

642   geophysical data are stored in Pangaea database at: **pending**.

Author contributions

644   RG performed the analysis and wrote the main manuscript file and figures. JS designed the research

645   project. PS dynamically assisted throughout the whole research process, during all stages of analysis and

646   interpretations of the cores. SF and FA led the bathymetric campaign and assisted the geophysical data

647   processing. RG, JS, SF, FA, SG sampled the cores. ALD assisted acquisition and interpretation of XRF

648   analysis. MŞ and SG provided invaluable assistance during the different field campaigns. CG and FN

649   provided the seismic data from a previous field campaign. JS, PS, SF, FA and CG actively corrected and

650   improved the manuscript. Each author has proofread and corrected the manuscript at least once.
