13

**Key Points:**

- Quantify chemical weathering and physical erosion fluxes for a mixed-lithology mountain range

- Physical erosion dominates the denudation signal and carbonate weathering dominates the weathering signal

- Precipitation of secondary carbonate is responsible for the loss of up to 90% of dissolved $[Ca^{2+}]$ in carbonate-rich rivers.

- Up to 90% of chemically weathered $Ca^{2+}$ is precipitated as solid secondary carbonate that becomes part of physical denudation flux

23

24 **Abstract**

25 Mixed siliciclastic and carbonate active orogens are common on Earth's surface, yet most studies

26 have focused on physical erosion and chemical weathering in silicate-rich landscapes. Relative to

27 purely siliciclastic landscapes, the response of erosion and weathering to uplift may differ in

28 mixed-lithology regions. However, our knowledge of weathering and erosion in mixed

29 carbonate-silicate lithologies is limited and thus our understanding of the mechanistic coupling

30 between uplift, chemical weathering, and the carbon cycle. Here, we partition the denudation

31 fluxes into erosion and weathering fluxes of carbonates and silicates in the Northern Apennine

32 Mountains of Italy—a mixed siliciclastic-carbonate active orogen—using dissolved solutes, the

33 fraction of carbonate sand in sediments, and existing $^{10}$Be denudation rates. Erosion fluxes are

34 generally an order of magnitude higher than weathering fluxes and dominate total denudation.

35 The contribution of carbonate and silicate minerals to erosion varies between lithologic units, but

36 weathering fluxes are systematically dominated by carbonates. Silicate weathering may be

37 limited by reaction rates, whereas carbonate weathering may be limited by acidity of the rivers

38 that drain the orogen. Precipitation of secondary calcite from super-saturated streams leads to the

39 loss of up to 90% of dissolved $Ca^{2+}$ from carbonate-rich catchments. Thus, in the weathering

40 zone, $[Ca^{2+}]$ is exceptionally high, likely driven by high soil $pCO_2$; however, re-equilibration

41 with atmospheric $pCO_2$ in rivers converts solutes back into solid grains that become part of the

42 physical denudation flux. Limits on weathering in this landscape therefore differ between the

43 subsurface weathering zone and what is exported by rivers.

44

45 **Plain Language Summary**

46 Erosion moves sediment across the surface and controls how natural resources (e.g. sand and

47 gravel) are generated. Conversely, the dissolution of rock in water (weathering) is the source for

48 nutrients and carbon transported in rivers. Understanding how total surface lowering

49 (denudation) is divided into weathering and erosion is important for establishing the link

50 between mountain-building processes and the generation of sediments and dissolved material.

51 Existing studies on denudation in mountainous ranges have primarily focused on landscapes

52 comprised of silicate rocks. However, many mountain ranges are characterized by mixed silicate-

53 carbonate rocks, and the processes that influence denudation of these landscapes may differ
54 relative to silicate-rich landscapes.

55 In this study, we separate measurements of denudation into erosion and weathering for the
56 Northern Apennine Mountains of Italy, a mixed-lithology mountain range. Similar to silicate-
57 rich landscapes, erosion is the dominant process here. Carbonate weathering dominates the total
58 weathering signal, and rock type is an important control on the amount of eroded carbonate
59 delivered to river channels. Most rivers are oversaturated in carbonate, therefore limiting the
60 amount that can be dissolved in rivers. This has resulted in the transformation of dissolved
61 material back into carbonate rock that is once again available to be eroded.

62

### 63  1 Introduction

64 Tectonically active orogens are responsible for the majority of sediments and solutes delivered
65 annually to the world's oceans (Milliman and Farnsworth, 2011; Larsen et al., 2014). Fresh rock
66 uplifted in mountain ranges is broken down by chemical weathering and physical erosion,
67 thereby creating soils, sediments, and solutes. Driven by topographic gradients, runoff then
68 transports these sediments and solutes to the surrounding floodplains and to the ocean. This
69 process is so fundamental to the cycling of rocks, nutrients, and carbon on Earth that changes in
70 the activity or spatial distribution of active orogens is frequently invoked to explain a variety of
71 phenomenon observed throughout Earth's history. For example, periods of icehouse and
72 greenhouse climates have been attributed to tectonic activity, because the uplift and erosion of
73 rock generates fresh mineral surfaces that become available for silicate weathering, thereby
74 modulating atmospheric $CO_2$ concentrations (Goddéris et al., 2017; Caves Rugenstein et al.,
75 2019).

76

77 The interplay between physical erosion and chemical weathering and its impact on the geological
78 carbon cycle is fundamentally controlled by the type of lithology that is exposed and eroded.
79 Previous studies on denudation fluxes in orogenic landscapes have focused on settings with
80 silicate-rich bedrock (Brandon and Vance, 1992; Granger et al., 1996; Kirchner et al., 2001;
81 Jacobson and Blum, 2003; Jacobson et al., 2003; Matmon et al., 2003; Moore et al., 2013;
82 Carretier et al., 2015; Emberson et al., 2017). In these landscapes, physical erosion fluxes

83   typically dominate the denudation signal by an order of magnitude relative to chemical
84   weathering fluxes (Riebe et al., 2001; Jacobson and Blum, 2003; West et al., 2005). Silicate
85   weathering fluxes are thought to increase with increasing denudation rates up to a limit, at which
86   point the sluggish kinetics of silicate dissolution lag behind the exposure of fresh mineral
87   surfaces (West et al., 2005; Gabet and Mudd, 2009). However, many active orogens today are
88   underlain not by pure silicate bedrock, but by either carbonate rock or interbedded siliciclastic
89   and carbonate sediments. The partitioning of denudation into physical erosion and chemical
90   weathering in these lithologies may be fundamentally different than the partitioning in silicate-
91   rich terranes. For example, the dissolution kinetics of carbonates are more than three orders of
92   magnitude faster than for silicates (Stallard and Edmond, 1987), and weathering fluxes are
93   globally dominated by carbonate weathering (Gaillardet et al., 1999). Even in places where
94   carbonate constitutes a minor component of the bedrock, carbonate weathering is frequently the
95   dominant source of cations (Sarin et al., 1989; Jacobson and Blum, 2003; Calmels et al., 2007;
96   Torres et al., 2016; Hilton and West, 2020). Importantly, carbonate and silicate weathering
97   produce different nutrients and soils (Ott, 2020) and differ in their impact on the carbon cycle.
98   Whereas silicate weathering is a carbon sink, on timescales longer than the calcium-
99   compensation time in the ocean, carbonate weathering is either carbon-neutral or is a carbon
100  source where dissolution occurs via sulfuric acid.

101

102  Existing weathering models based on silicate-rich settings are typically parameterized as supply-
103  limited for lower denudation rates, where weathering and erosion are coupled, and kinetically
104  limited at faster denudation rates, where weathering and erosion are decoupled (West et al.,
105  2005). In contrast, because of more rapid kinetics, carbonate weathering is unlikely to be
106  kinetically limited and, instead, is either limited by the supply of fresh rock or by the availability
107  of acid (primarily carbonic acid) that can dissolve carbonate rock (Calmels et al., 2011;
108  Gaillardet et al., 2018; Romero-Mujalli et al., 2018). The supply of acid is controlled by a
109  number of factors, including temperature, the efficiency of soil respiration that supplies $CO_2$ for
110  carbonic acid to the bedrock, and the oxidation of sulfates that creates sulfuric acid. Both the
111  total $CO_2$ available for weathering and the temperature control the saturation of the solution with
112  respect to calcite (Drake and Wigley, 1975). Thus, for undersaturated fluids, carbonate
113  weathering may be strongly coupled with erosion, whereas it becomes decoupled from erosion
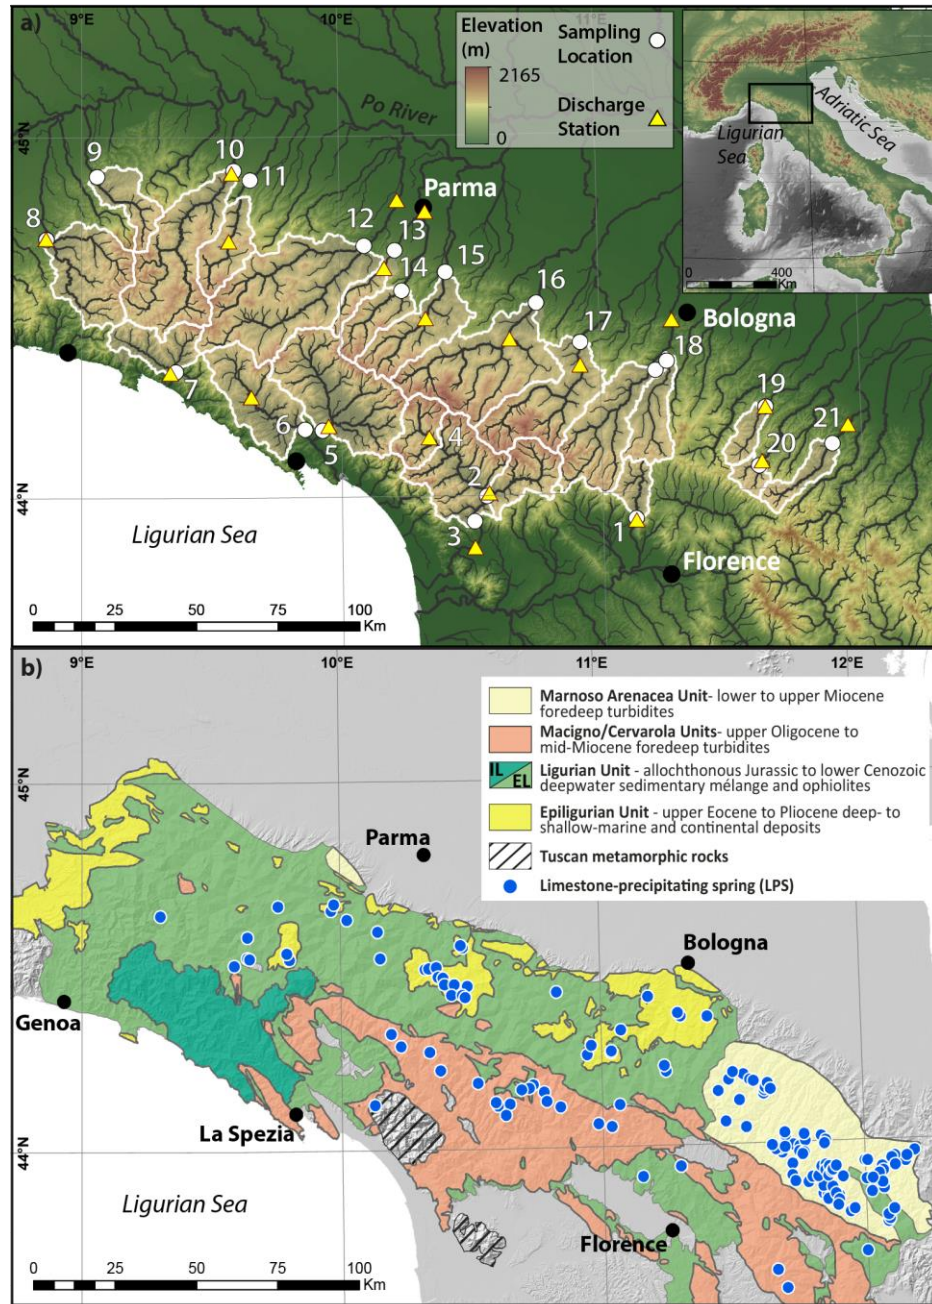

114    and coupled to acid availability, once saturation is achieved. As a consequence, the mechanisms

115    that control how denudation is partitioned in a dominantly carbonate orogen may differ

116    substantially from those that control denudation partitioning in silicate orogens (Gaillardet et al.,

117    2018; Ott et al., 2019).

118

119    Young orogens in particular often expose marine sedimentary sequences that can host significant

120    volumes of carbonate, either as massive carbonate terranes or interbedded with siliciclastic

121    sediments. For example, the entire Alpine-Zagros-Himalayan orogenic complex has a common

122    genesis during the Mesozoic, when carbonate platforms covered a large area of the Tethys

123    Ocean. These carbonates have been subsequently uplifted during the ongoing closure of the

124    Tethys Ocean in the Cenozoic (Dercourt and Vrielynck, 1993; Philip et al., 1996). Yet, because

125    such ranges are poorly represented in existing studies, we lack the ability to understand how

126    uplift of such ranges may impact biogeochemical cycling and sediment budgets. Indeed, cooling

127    during the Cenozoic is frequently attributed to the uplift of mountains, but if the majority of

128    active ranges in the Cenozoic are comprised of carbonate-rich bedrock, the mechanistic coupling

129    between mountain uplift and cooling—and subsequent impact on the carbon cycle—may require

130    revision.

131

132    In this paper, we investigate the partitioning of physical and chemical denudation between

133    carbonates and silicates in a carbonate-rich orogen, the Northern Apennines (Figure 1). To this

134    end, we use existing [10]Be catchment-averaged denudation rates (Cyr and Granger, 2008; Cyr et

135    al., 2014; Wittmann et al., 2016; Erlanger, 2020), riverine dissolved solutes, and the fraction of

136    carbonate sand in river sediment in 18 individual catchments draining the Northern Apennines.

137    The results from this study reveal four key characteristics of denudation partitioning: (1) physical

138    erosion dominates the total denudation flux in the Northern Apennines, and the relative

139    contribution of carbonates and silicates to the physical erosion flux appears to be lithologically

140    controlled, (2) denudation fluxes are decoupled from both silicate and carbonate weathering,

141    likely due to kinetic limitations on silicate weathering and acid-supply limits on carbonate

142    weathering,  (3) the carbonate weathering flux is greater than the silicate weathering flux, and (4)

143    in carbonate-rich catchments, up to 90% of dissolved $Ca^{2+}$ ions are precipitated as secondary

144  calcite, an important process that converts chemically mobilized solutes back into solid grains

145  that can once again be transported physically.

146

147
148  **Figure 1**. a) Overview map with locations of sampled sediment and water (white circles) and
149  discharge stations (yellow triangles). White polygons illustrate the sampled catchment area for
150  sediment and water samples, and numbers correspond to catchment names given in all
151  manuscript tables. b) Geologic map of the Northern Apennines. The Ligurian Unit is divided into
152  the Internal Ligurian Unit (IL; dark green) and the External Ligurian Unit (EL; light green). Gray

153 areas are not mapped and white area represents the Ligurian Sea. Limestone-precipitating springs
154 mapped by Cantonati et al. (2016) and Segadelli and De Nardo (2018) are shown as blue dots.
155

156 **2 Setting**

157 **2.1 Geology**

158 The Northern Apennines form part of the Alpine orogenic belt and were uplifted and sub-aerially

159 exposed by ~4–5 Ma (Le Pichon et al., 1971; Fellin et al., 2007). This mountain range is a type

160 example for the initial stages of orogenesis, characterized by an intact sedimentary cover of

161 mixed siliciclastic-carbonate lithologies, with little to no metamorphic rocks and relatively low

162 relief. Lithologies exposed in the Northern Apennines are dominated by marine sedimentary

163 sequences deposited as turbidites (Tertiary Foredeep units), which are divided into the Macigno,

164 Cervarola, and Marnoso Arenacea Units (Figure 1b). Overlying these deposits are remnants of

165 the Ligurian Tethys Ocean (Ligurian Unit), comprised of pelagic successions and turbidites (Vai

166 and Martini, 2001). The Ligurian Unit is subdivided into (1) the External Ligurian Unit (EL),

167 which consists of clayey shales, carbonaceous and siliciclastic turbidites, and (2) the Internal

168 Ligurian Unit, which consists of pelagic limestone, sandstone, and minor ophiolites (Ricci

169 Lucchi, 1986; Molli, 2008). Overlying the EL, mixed siliciclastic and carbonate deposits formed

170 in perched basins from the mid-Eocene to the Pliocene, and comprise the so-called Epi-Ligurian

171 Unit.

172

173 We refer to the northeast flank of the mountain range as the Adriatic side, where all rivers drain

174 into the Po Plain and ultimately to the Adriatic Sea, and refer to the southwest flank as the

175 Ligurian side, where rivers drain into the Ligurian Sea (Figure 1a). On the Adriatic side,

176 limestone-precipitating springs (LPS) have been mapped mostly in the Tertiary Foredeep and

177 Epi-Ligurian units (Figure 1b) and are associated either with perched, isolated aquifers formed

178 from slope-gravitational movements, or with aquifers formed along fault planes (Cantonati et al.,

179 2016). Other LPS have been observed in the Ligurian Units and are also associated with

180 gravitational processes (i.e. landslides) that are a common occurrence in these lithologies (Carlini

181 et al., 2016; Segadelli et al., 2017).

182

183 **2.2 Climate**

184    The climate in the Northern Apennines is characterized as Mediterranean, with average
185    temperatures of ~10°C. Average January temperatures are 0°C in the mountains and up to 10°C
186    on the Ligurian coastlines, compared with a more spatially consistent July average of 15–20°C
187    (Brunetti et al., 2014). Precipitation primarily falls as snow or winter rain, with a maximum
188    (300–800 mm) during the months of September through February, and a minimum (150–300
189    mm) during the months of June through August (Crespi et al., 2018). During the fall, winter, and
190    spring, precipitation is approximately a factor of 2 higher on the Ligurian side and in the highest
191    elevations on the Adriatic side, relative to the middle and lower reaches of catchments on the
192    Adriatic side (Crespi et al., 2018). During the summer months (June, July and August), seasonal
193    precipitation is similar across the divide (250-350 mm) in the Northern Apennines (Crespi et al.,
194    2018).

195

196    Maximum river discharge occurs during the months of November to March. Average annual
197    runoff (discharge divided by upstream catchment area) compiled for each studied catchment over
198    the last five available years is ~1.2–2.2 m/yr along Ligurian rivers. Runoff and denudation
199    typically illustrate a positive correlation (Summerfield and Hulton, 1994), although catchment-
200    averaged denudation rates and runoff from Northern Apennine rivers appear to be negatively
201    correlated (Figure S1).

202

203    **3 Materials and Methods**

204    **3.1 Water Chemistry**
205    In order to quantify chemical weathering and physical erosion fluxes, we collected water samples
206    and sediment samples from the Northern Apennines. For the water samples, we measured solute
207    concentrations, which are multiplied with estimated river runoff to obtain weathering fluxes. We
208    sampled sediment from active channels and overbank deposits during two sampling seasons in
209    March and July of 2018. These two months broadly correspond to the times of yearly minimum
210    and maximum runoff and were chosen to bracket as much as possible the yearly range of
211    streamflow conditions. Sampling sites were chosen near locations with existing constraints on
212    catchment-averaged denudation rates (Figure 1a). Additionally, over the course of four sampling
213    campaigns (May 2017, July 2017, March 2018, and July 2018), we collected three 30 mL bottles

214    of river water at each sample location. All water samples were filtered through 0.2 μm VWR

215    filters. Cation samples were acidified with laboratory-grade HCl to a pH of 2 or lower, and all

216    samples were kept cool and away from light until analysis. Alkalinity was measured in the field

217    (maximum 24 hours after collection) for most samples using either end-point or Gran titration

218    techniques with a Hach digital titrator. Cation concentrations of water samples were analyzed on

219    a Thermo-Fischer Element XR sector-field inductively-coupled-plasma (ICP) mass spectrometer.

220    Concentrations were then calculated from the measured intensities, using a single-point

221    calibration compared with an in-house primary standard. In-house standards were calibrated with

222    the Certified Reference Standards of DIONEX. The National Research Council of Canada river

223    standard SLRS-6 and NIST 1640 secondary multi-element standards were used to assess the

224    accuracy and precision of these measurements. Standards solute concentrations agree with

225    certified values to within 5–10%, and $2\sigma$ uncertainties for replicate analyses of the standards

226    were less than 7%.

227

228    Anion concentrations and cation replicates were analyzed on a Dionex DX-120 ion

229    chromatography (IC) instrument, with an IonPac AS14, 4 x 250 mm column and an ASRIS-Ultra

230    Suppressor with AutoSuppression. To prepare all eluents of $NaCO_3$, deionized water (with a

231    resistance of higher than 18.2 MΩ) from a Milli-Q water unit was used. For all anions and

232    cations, analytical uncertainties were below 5%.

233

234    **3.2 Catchment-Averaged Denudation Rates**

235    Detrital, catchment-averaged denudation rates derived from [10]Be concentrations were compiled

236    from catchments around the Northern Apennines (Cyr and Granger, 2008; Cyr et al., 2014;

237    Wittmann et al., 2016; Erlanger, 2020). Due to the fact that these samples were collected over

238    different years and assume different cosmogenic nuclide scaling schemes to calculate denudation

239    rates, we use the denudation rates given in Erlanger (2020), which includes rates from other

240    studies (Cyr and Granger, 2008; Cyr et al., 2014; Wittmann et al., 2016) that were recalculated

241    using the method of Lupker et al. (2012). All denudation rates were then converted to fluxes

242    using a quartz density of 2.65 g/cm$^3$.

243

244    **3.3 Carbonate Sand**

245    Sediment samples were cleaned to remove organic matter and sieved to obtain the 250–500 μm

246    fraction. We used grain sizes within the range of the [10]Be denudation rates (125–700 μm), in

247    order to avoid potential grain size bias when comparing silicate and carbonate weathering and

248    erosion fluxes. Approximately 50 g of sand (or the available mass) was weighed and dissolved in

249    HCl. The remaining mass was rinsed, dried, and weighed. The difference between the original

250    and final mass was assumed to represent the percent carbonate within the sand-sized fraction.

251

252    **3.4. Water Solute Corrections and Calculations**

253    For some catchments, we collected a repeat sample from the same location during both the

254    winter and summer season. Where appropriate, when we discuss results from one of the repeat

255    measurements, we refer to an individual "sample". When the collective set of sample(s) from a

256    catchment are discussed, we refer to the "catchment".

257

258    Solute concentrations were initially corrected to account for rainwater inputs. We additionally

259    assess the saturation state of the samples with respect to calcite, because the widespread presence

260    of travertine deposits and limestone-precipitating springs in the Northern Apennines (Figure 1b)

261    (Cantonati et al., 2016; Segadelli and de Nardo, 2018) suggests that waters in many catchments

262    may be oversaturated with respect to calcite.

263

264    **3.4.1 Cyclic Inputs**

265    We corrected our solute concentrations for rainwater inputs using atmospheric Cl$^-$ as an index for

266    atmospheric inputs to rivers. For large rivers that integrate sizable catchments, water chemistry

267    data suggest that atmospheric Cl$^-$ concentrations should be lower than 30 μmol/L (Gaillardet et

268    al., 1999). Due to the proximity of the Northern Apennines to the Ligurian and Adriatic Seas, the

269    seawater contribution of Cl$^-$ may be higher than 30 μmol/L. The lowest measured Cl$^-$

270    concentration is 64.6 μmol/L. We assume that this value is representative of the rainwater

271    contribution to all rivers and correct major dissolved species for rainwater inputs using the

272    stoichiometry of seawater. For sulfate, we assume that sulfate-chloride ratios in rain are twice as

273    high as in seawater, following Stallard and Edmond (1981).

274

275    **3.4.2 Saturation Index**

276    The saturation index (SI) of a solution is defined as (Langmuir, 1971):

277

278 $$SI_{calcite} = \log(IAP_{calcite}/K_{calcite}) \tag{1}$$

279

280 $$IAP_{calcite} = a_{Ca} \cdot a_{HCO_3} \cdot K_2/10^{-pH} \tag{2}$$

281

282    where IAP is the ionic activity product, $K_{calcite}$ is the equilibrium constant for carbonate, $a_{Ca}$ and

283    $a_{HCO3}$ are the activities of $Ca^{2+}$ and $HCO_3^-$ (Davies and Shedlovsky, 1964), and $K_2$ is the second

284    dissociation constant of $H_2CO_3$. Here, we assume that the concentrations of $Ca^{2+}$ and $HCO_3^-$ are

285    equal to the activities.

286

287

288    **3.5 Calculation of denudation fluxes**

289    Denudation, weathering, and physical erosion fluxes were calculated for 25 samples from 18

290    catchments. We excluded samples from these calculations due to unavailable carbonate sand

291    measurements (River No. 4); unavailable discharge data (River No. 9); unavailable denudation

292    measurements (Cutigliano sample from River No. 2 and the Castello di Sambuca from River No.

293    18); textile pollution in River No. 1, based on elevated Na+ and $SO_4^{2-}$ (Cortecci et al., 2002), for

294    which we cannot confidently correct; or to "contamination" by evaporite weathering (Text S1),

295    based on mapped distributions of evaporites in these catchments,.

296

297    For silicate weathering, the contribution of major dissolved ions was calculated by summing the

298    concentrations of the following species, expressed as major cations and silicon derived from

299    silicate rocks (expressed in kg/m$^3$ or g/L):

300

301 $$TDS_{sil} = [Ca^{2+}]_{Sil} + [Mg^{2+}]_{Sil} + [Na^+]_{Sil} + [K^+]_{Sil} + [Si] \tag{3}$$

302

303    Here, the square brackets designate concentrations. We refer to this quantity as "silicate

304    dissolved solids" ($TDS_{Sil}$). Because $Ca^{2+}$ and $Mg^{2+}$ can be derived from both carbonate and

305    silicate weathering, we partitioned the concentrations based on molar ratios from a global

306    compilation of streams draining pure silicate lithologies $Ca_{sil}/Na$ (0.35) and $Mg_{sil}/Na$ (0.24)

307    (Gaillardet et al., 1999). In the absence of local constraints, this global silicate endmember

308    appears to be a fair approximation of the local endmember in the Northern Apennines (Figure

309    S3). Furthermore, we find no local lithological data which supports the use of a single

310    endmember for the entire group of data (Figure S3).

311

312     The silicate chemical weathering flux (in t/km$^2$/yr) is calculated using the following equation:

313

314    $W_{Sil} = \frac{Q_{riv}*TDS_{Sil}}{A_{riv}} = \frac{Q_{riv}}{A_{riv}} * \left( M_{Na}*[Na^+]_{sil} + M_K*[K^+]_{sil} + M_{Mg}*[Mg^{2+}]_{sil} + M_{Ca}*[Ca^{2+}]_{sil} + \right.$

315                    $\left. + M_{Si}*[Si] \right)$                                                                 (4)

316

317    where $M_x$ is the molar mass (g/mol) of element X, and $Q_{riv}/A_{riv}$ is the runoff, expressed as the

318    time-integrated water discharge (m$^3$/y) divided by the upstream drainage area (m$^2$).

319

320    For carbonate weathering, the concentrations of $Ca^{2+}_{carb}$ and $Mg^{2+}_{carb}$ are assumed to be the

321    difference between the total concentrations and the silicate contribution. We define the

322    "carbonate dissolved solids" (TDS$_{Carb}$) as:

323

324     $TDS_{carb} = [Ca^{2+}]_{Carb} + [Mg^{2+}]_{Carb} = ( [Ca^{2+}]_{Total} + [Mg^{2+}]_{Total}) - ([Ca^{2+}]_{Sil} + [Mg^{2+}]_{Sil})$     (5)

325

326    The carbonate weathering flux (W$_{Carb}$) is then calculated using equation 6:

327

328            $W_{Carb} = \frac{Q_{riv}*TDS_{Carb}}{A_{riv}} = \frac{Q_{riv}}{A_{riv}} * \left( M_{Mg}*[Mg^{2+}]_{Carb} + M_{Ca}*[Ca^{2+}]_{Carb} \right)$                    (6)

329

330    The total denudation flux (D) is defined as the sum of chemical weathering fluxes (W$_{Carb}$ + W$_{Sil}$)

331    and the physical erosion flux (E) (Equation 7). Although $^{10}$Be denudation rates record the

332    exhumation of quartz grains, we assume that these rates reflect the lowering rate over the entire

333    catchment, and thereby apply to both siliciclastic and carbonate lithologies. In the Northern

334    Apennines, carbonates occur both interbedded with and as accessory minerals within siliciclastic

335    lithologies, and no steep carbonate cliffs or large areas that drain exclusively quartz or carbonate

336    lithologies are reported here. We also assume that the sand fraction—and the fraction of silicate

337    and carbonate within this fraction—represent the partitioning of erosion between silicates and

338    carbonates. We thus refer to the erosional flux within the sand-sized fraction as the "total
339    physical erosion", which is expressed as:
340
341    $$E_{total}=D - (W_{sil}+ W_{carb}) \qquad\qquad (7)$$
342
343    To partition the physical erosion flux into carbonates and silicates, we use the percent carbonate
344    sand determined for each river to obtain the carbonate erosion flux:
345
346    $$E_{carb}=E_{total}* \%Sand_{carb} \qquad\qquad (8)$$
347
348    and:
349
350    $$E_{sil}=E_{total}- E_{carb} \qquad\qquad (9)$$
351
352    We propagate uncertainties of all quantities from the analytical and reported uncertainties of the
353    underlying measurements.
354
355    **4 Results**
356    **4.1 Carbonate Sand**
357    Catchment-wide percent carbonate sand varies from 17–76% (Figure 2, Table S1) and values
358    observed here are consistent with point counts of lithic carbonate sand grains (Lc) observed in
359    these catchments (Garzanti et al., 1998, 2002) (Table S1). Catchments that exclusively drain the
360    same geologic unit have similar percent carbonate sand. For example, the carbonate content of
361    catchments draining the Internal Ligurian Unit (6–7) ranges from 17–18%; catchments draining
362    the Macigno/Cervarola Unit (1–3), 20–28%; catchments draining the Marnoso Arenacea (19–
363    21), 21–42%, and; catchments draining the EL (9–10 and 12–13), 60–76%. Sampled catchments
364    that drain a mixture of units generally have carbonate sand percentages outside the range of those
365    that exclusively drain one lithology (Figures 1–2). We also find a strong positive correlation ($R^2$
366    = 0.82) between the percent carbonate sand and the areal exposure of the EL within a catchment
367    (Figure 3).
368

**Figure 2**. Percent carbonate sand for each catchment. Numbers correspond to catchment numbers in Table S1. The hatched pattern corresponds to River No. 4, for which data were not available. The light green color beneath the hatched pattern corresponds to River No. 3, which encompasses River No. 2 and 4.

**Figure 3.** Catchment area that exposes the EL plotted against percent carbonate sand. Numbers in parentheses indicate the river number as shown in Figure 1a.

378

### 4.2 Solutes

379
380  Riverine samples from the Northern Apennines are slightly alkaline, with pH values ranging
381  from 7.7–9.1, and major dissolved ion concentrations that are dominated by $Ca^{2+}$ and $HCO_3^-$
382  (Table S2). Most catchments have SI values greater than zero (Figure 4, Table S3), which
383  indicates that the waters are oversaturated with respect to calcite. The lowest SI values (<0)
384  reflect undersaturated conditions and are sourced exclusively from catchments on the Ligurian
385  side of the drainage divide.

386

387
388  **Figure 4**. Histogram of saturation index results. Undersaturated samples (blue bars) have values
389  below zero, saturated samples (green bar) are at saturation, and oversaturated samples (orange
390  bars) have values above zero. The hatched pattern refers to the River No. 1, which is affected by
391  pollution from nearby textile industries (Cortecci et al., 2002) and produced high ion
392  concentrations that could not be attributed to natural sources.

393

### 4.3 Erosion and Weathering Fluxes

394
395  Total denudation fluxes derived from [10]Be concentrations vary over an order of magnitude, from
396  278–2226 $t/km^2/yr$ (Table 1). Total physical erosion fluxes ($E_{Total}$) range from 121–2151
397  $t/km^2/yr$. Partitioned into carbonate physical erosion ($E_{Carb}$) and silicate physical erosion ($E_{Sil}$),
398  the ratio of $E_{Carb}/E_{Sil}$ varies from 0.21–3.35, where 52% of samples have higher $E_{Sil}$ fluxes than
399  $E_{Carb}$ fluxes (Table 1).

400

401    Total weathering fluxes ($W_{Total}$) vary from 38–165 t/km$^2$/yr (Table 1). $E_{Total}/W_{Total}$ is 24.0 on

402    average, illustrating that physical erosion fluxes generally exceed chemical weathering fluxes by

403    up to an order of magnitude. Carbonate weathering fluxes ($W_{Carb}$ = 19–93 t/km$^2$/yr) are higher

404    than the silicate weathering fluxes ($W_{sil}$ = 9–72 t/km$^2$/yr). The ratio of $W_{Carb}/W_{Sil}$ varies from

405    0.95– 4.77, and is greater than 1 for all catchments, except River No. 19. The average ratio of

406    $W_{Carb}/W_{Sil}$ = 2.35, illustrating that carbonate weathering fluxes are on average a factor of 2

407    higher than silicate weathering fluxes.

408

**Table 1.** Denudation fluxes, physical erosion fluxes, and chemical. weathering fluxes.

| Catchment Number | Catchment Name | Sample Number | Latitude | Longitude | Sampling Date | D (t/km²/yr) | W_Total (t/km²/yr) | W_Carb (t/km²/yr) | W_Sil (t/km²/yr) | E_Total (t/km²/yr) | E_Carb (t/km²/yr) | E_Sil (t/km²/yr) | Annual Runoff (m/yr) | W_Total/E_Total | E_carb/E_sil |

D = Denudation flux (physical erosion + chemical weathering); W_Total = Total Weathering Flux; W_Carb = Carbonate Weathering Flux; W_Sil = Silicate Weathering Flux; E_Total = Total Physical Erosion flux;

E_Carb = Carbonate Physical Erosion Flux; E_Sil = Silicate Physical Erosion Flux.

ND = Fluxes not determined for sample due to lack of carbonate sand measurements

409

410  **4.4 Partition of Denudation between Carbonates and Silicates**

411  Here, we compare denudation fluxes, total dissolved solids (TDS) as a proxy for chemical

412  weathering, and the percent carbonate sand as a proxy for carbonate physical erosion. In each

413  figure, we plot the entire set of samples, but differentiate between catchments draining the EL

414  (gray circles), defined as catchments where the EL constitutes at least 50% of the exposed

415  lithologies, from all other units (cyan circles). Additionally, we distinguish between

416  oversaturated samples (solid pattern) and undersaturated/saturated samples ("x" pattern).

417        For catchments draining the EL, we find that percent carbonate sand does not scale with

418  denudation fluxes (gray circles, Figure 5a). In turn, denudation fluxes illustrate a decoupling with

419  carbonate dissolved solids, $TDS_{Carb}$, and only a weak correlation with silicate dissolved solids,

420  $TDS_{Sil}$ ($R^2$=0.27), and total dissolved solids, $TDS_{Total}$ ($R^2$=0.34) (Figure 5b-d). However, we find

421  a strong correlation, albeit with low significance (p=0.07) due to the small sample size, between

422  carbonate weathering and denudation fluxes in all undersaturated/saturated samples (x pattern)

423  ($R^2$=0.85) (Figure 5d). Similarly, $TDS_{Carb}$ and the percent carbonate sand are decoupled for

424  oversaturated catchments (Figure 6) but illustrate a moderate correlation ($R^2$=0.71) for

425  undersaturated samples (x pattern), although the significance is again low (p=0.16).
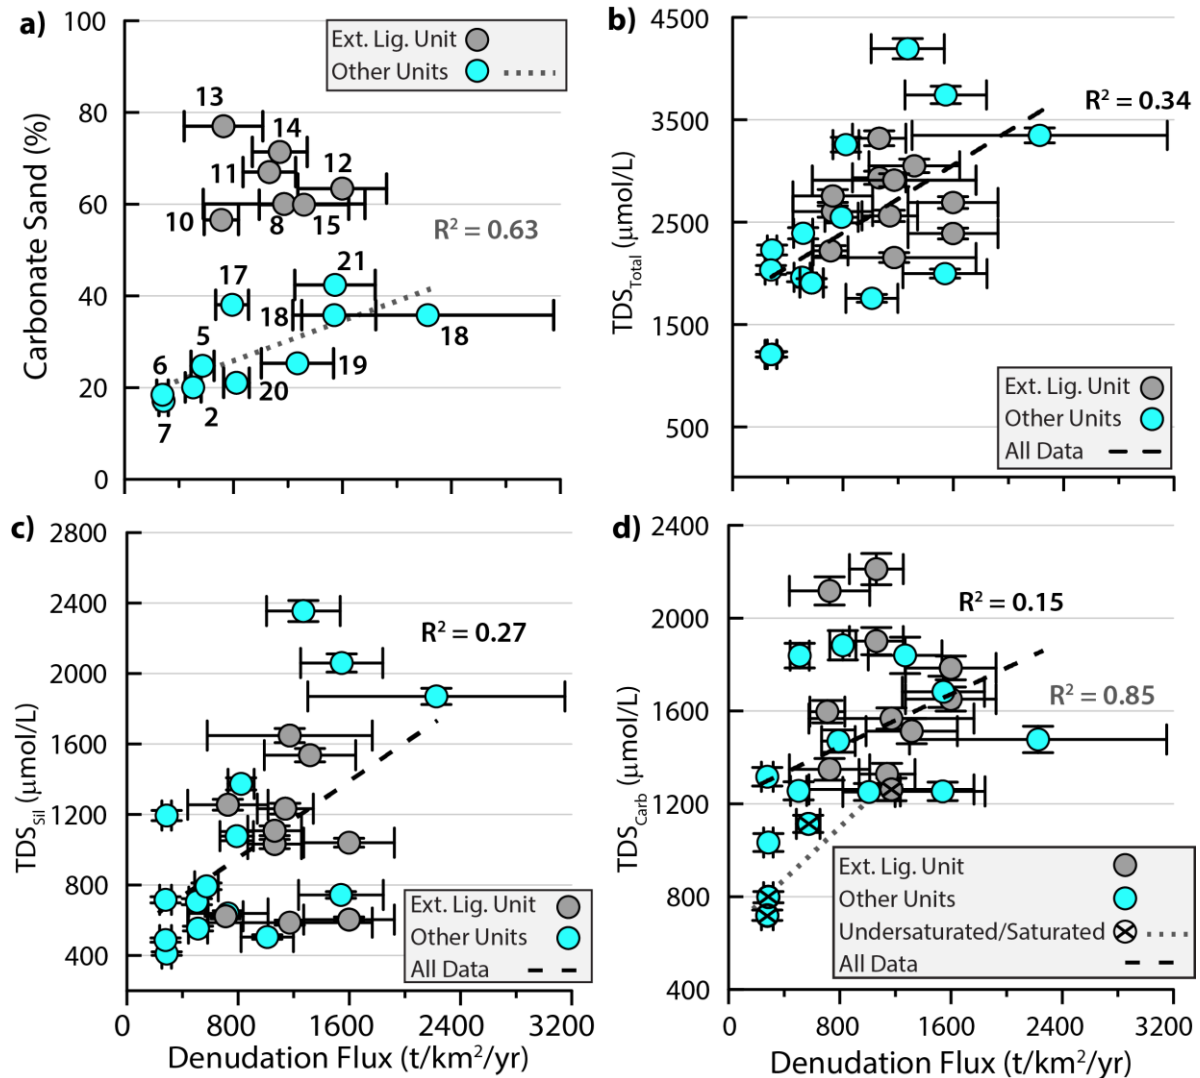

426
427 **Figure 5**. Denudation fluxes plotted against a) percent carbonate sand, b) TDS$_{Total}$ c) TDS$_{Sil}$, and
428 d) TDS$_{Carb}$. EL samples (gray circles) are differentiated from Other Units (cyan circles). Dashed
429 lines illustrate linear regressions for each full dataset with associated R$^2$ statistic. In a) dotted line
430 refers only to samples from Other Units (cyan circles) (R$^2$=0.56), and numbers refer to
431 catchments shown in Figure 1a. In d) solid circles illustrate oversaturated samples;
432 undersaturated/saturated samples are overlaid with a "x". The dotted line (R$^2$=0.85) refers only to
433 undersaturated/saturated samples.
434

**Figure 6.** Percent carbonate sand plotted against TDS$_{Carb}$. The EL (gray circles) are distinguished from other lithologic units (red circles). Oversaturated samples are shown as solid circles; undersaturated and saturated samples are overlaid with a "x". Linear regressions and $R^2$ statistics are only shown for the undersaturated/saturated samples ($R^2$=0.71).

**5 Discussion**

In the following discussion, we investigate the mechanisms that control how denudation is partitioned between erosion and weathering and between carbonates and silicates and compare denudation and weathering fluxes from the Northern Apennines with a global data compilation from silicate-rich landscapes.

In the Northern Apennines, physical erosion is the dominant denudational process, and ratios of $E_{Carb}/E_{Sil}$ are variable, suggesting that both erosion of carbonates and silicates is important in this landscape (Table 1). However, we observe some important lithologic controls on carbonate erosion. In particular, the highest carbonate sand percentages (67–76%) are found in catchments exclusively draining the EL (Figure 2), and the percent carbonate sand and areal coverage by the EL illustrate a strong linear correlation (Figure 3), suggesting that the EL is the most important source of carbonate sand grains to river channels in the Northern Apennines.

However, we find no obvious lithologic control on the partitioning of chemical weathering and denudation (Figure 5b–d). Silicate and carbonate weathering fluxes (TDS x runoff) are uncorrelated with denudation, which could be explained by the negative correlation we observe between denudation and runoff (Figure S1). Along with the observed weak coupling or decoupling between weathering proxies and denudation fluxes, these findings are consistent

458    with a limitation for both silicate and carbonate weathering at erosion rates characteristic of the

459    Northern Apennines or higher. A kinetic limitation of silicate weathering rates has previously

460    been suggested for denudation rates >48 t/km$^2$/yr (West et al., 2005). Based on the widespread

461    oversaturation of sampled waters with respect to calcite, we suspect that carbonate weathering

462    rates are most likely limited by the availability of acid. As long as acid availability does not

463    increase with erosion rate, weathering rate and denudation should be decoupled, consistent with

464    our observations. The decoupling between carbonate weathering rate and denudation fluxes for

465    oversaturated samples and possible strong correlation with undersaturated/saturated samples

466    (Figure 5d) further supports the hypothesis that the carbonate weathering rate is not kinetically

467    limited, but is instead either limited by the supply of carbonates (undersaturated/saturated

468    samples) or the availability of acid (oversaturated samples).

469

470    **5.2 Global Comparison with Silicate-Rich Orogens**

471    Relative to other silicate-rich orogens with similar denudation fluxes (e.g. Eastern Southern Alps

472    of New Zealand, Colorado Rockies, Swiss Alps, and Andes Mountains), weathering fluxes (Text

473    S2) are generally higher in the Northern Apennines (red circles; Figure 7).

474

475   **Figure 7**. Northern Apennines denudation fluxes and total weathering fluxes plotted against a
476   global data compilation. Triangles illustrate physical erosion fluxes derived from suspended
477   sediment or average annual sediment fluxes, and circles illustrate denudation rates derived from
478   cosmogenic nuclide data.

479

480   We compare our fluxes in more detail with those from the Eastern Southern Alps of New

481   Zealand (ESA), as both regions are in temperate climates and weathering fluxes partitioned into

482   carbonate and silicate components are also available for the Southern Alps (Jacobson and Blum,

483   2003). Physical erosion fluxes from the ESA (140–1700 $t/km^2/yr$) are similar to estimates from

484   the Northern Apennines (129–2153 $t/km^2/yr$). However, the ratio of physical erosion to total

485   weathering ($E_{Total}/W_{Total}$) in the ESA ranges from 9–150, with an average of 64, reflecting

486   weathering fluxes that are 1–2 orders of magnitude lower than physical erosion fluxes. Average

487   ratios of erosion to weathering fluxes ($E_{Total}/W_{Total} = 24.0$) are lower in the Northern Apennines,

488   reflecting the more important role of carbonate weathering in this setting. Carbonate weathering

489   fluxes range from 8–100 $t/km^2/yr$ in the ESA, compared with the range of 19–93 $t/km^2/yr$ found

490   in the Northern Apennines. Although the ESA are dominated by silicate-rich greywacke and

491   schist lithologies with minor hydrothermal calcite veins, the ratio of carbonate to silicate

492   weathering ($W_{Carb}/W_{Sil}$) is >1 for all except one sample, and has an average ratio of $W_{Carb}/W_{Sil} =$

493   1.63. In the Northern Apennines, $W_{Carb}/W_{Sil} = 2.35$—approximately a factor of 1.5 higher

494   relative to the ESA— and we suggest that the difference in ratios between these two setting is

495   due to lithologic differences. A lack of carbonate in stream sediments of the Southern Alps

496   implies that carbonate weathering is likely supply-limited. In contrast, in the Northern

497   Apennines, exported solutes from carbonate weathering appear to be limited by acid availability,

498   rather than mineral supply. The current weathering state (i.e. the exported flux to rivers) in the

499   Northern Apennines is thus one that is generally decoupled from mineral supply and entirely

500   controlled by the kinetics of silicate dissolution (which modulates silicate weathering) and acid

501   availability (which modulates carbonate weathering).

502

503   **5.3 Limits on Weathering and Erosion in the Northern Apennines**
504   **5.3.1 Secondary Calcite**

505   As in carbonate-rich terranes globally, we observe that the vast majority of Northern Apennine

506   waters are oversaturated with respect to calcite. When soil waters equilibrate at high $CO_2$ partial

507    pressures ($p$CO$_2$) in the subsurface and are discharged to streams, they begin to de-gas excess

508    CO$_2$ to equilibrate with the lower atmospheric $p$CO$_2$. The resulting supersaturation of the waters

509    with respect to the dissolved carbonates leads to the secondary precipitation of calcite (Bickle et

510    al., 2015). The abundance of limestone-precipitating springs (Figure 1b) suggests that subsurface

511    waters in the Northern Apennines are typically supersaturated in carbonates. Furthermore, we

512    observe that a substantial fraction of the sand grains from the Lamone River are secondary

513    carbonate sand grains (Figure S6), suggesting that precipitation and erosion of secondary

514    carbonates is a major process in the Northern Apennines. Cavazza et al. (1993) similarly

515    observed that up to 35% of the sand fraction in the Senio River (River No. 19) are such

516    secondary carbonate "peloid" grains, comprised of organic material or quartz grains in the core

517    and coated by a carbonate crust. Secondary calcite precipitation converts solutes back into rock

518    that can be physically eroded—hence, it is a process that can potentially decouple the controls on

519    weathering within the weathering zone from what is exported by rivers from the orogen. Further,

520    by estimating the degree of secondary carbonate precipitation that occurred upstream of our

521    sampling locations, we can quantify the flux of initially weathered material that has been

522    subsequently converted back to solid grains and is no longer recorded in the flux of exported

523    solutes in the river.

524

525    We estimate the proportion of secondary calcite precipitation in each lithology, adopting the

526    procedures of Bickel et al. (2015) (Text S2). All quantities that include the inferred concentration

527    of solutes lost to secondary precipitation are designated by an '*' (e.g. TDS$_{Total}$*) and are

528    referred to as weathering zone fluxes. We use $\gamma$ to describe the proportion of calcium measured

529    at our sampling location, relative to the inferred total calcium weathered from bedrock

530    (Emberson et al., 2018). A value of $\gamma=1$ indicates that no secondary precipitation can be inferred

531    from the chemical composition, and a value of $\gamma=0$ corresponds to the (hypothetical) situation in

532    which all calcium was lost to secondary calcite precipitation. Oversaturated samples have

533    average $\gamma$ values between 0.1–0.8, which indicates that between 20–90% of [Ca$^{2+}$] was lost to

534    secondary calcite precipitation (Figure 9). Catchments draining the EL illustrate the largest offset

535    between the solute regression line and bedrock regression line (Figure S4d), which results in the

536    greatest corrections to [Ca$^{2+}$].

537

538

539

**Figure 9**. Results from secondary calcite precipitation calculations, showing $\gamma$ plotted against $TDS_{Total}*$ for major dissolved ions and trace elements, calculated with the adjusted $[Ca^{2+}]$. Samples with an "x" were not corrected for secondary calcite precipitation.

**5.3.2 Weathering Zone Fluxes**

Total weathering zones fluxes ($W_{Total}*$) vary from 63–602 $t/km^2/yr$ (Table 2). The average ratio of total erosion fluxes to these weathering fluxes ($E_{Total}/W_{Total}* = 4$) is a factor of 6 lower relative to the average ratio for the exported fluxes ($E_{Total}/W_{Total} = 24$).

Here, we illustrate the results in terms of the weathering zone total TDS concentrations ($TDS_{Total}*$) and weathering zone carbonate dissolved solids ($TDS_{Carb}*$). Note that the estimated concentrations from silicate dissolved solids ($TDS_{Sil}$) are unaffected by the correction for secondary calcite precipitation. $TDS_{Carb}*$ constitutes 70–97% of $TDS_{Total}*$, and both measures are decoupled from denudation fluxes when considering the entire dataset (Figure 10a-b). Catchments draining the EL (gray circles) are characterized by the highest $TDS_{Total}*$ values and are also decoupled from denudation. In turn, oversaturated samples from non-EL units illustrate a weak correlation between denudation and $TDS_{Total}*$ ($R^2=0.32$, $p=0.11$) and $TDS_{Carb}*$ ($R^2=0.30$, $p=0.12$) (Figure 10a-b). Finally, we observe a moderate correlation between $TDS_{Carb}*$ and the percent catchment area covered by the EL ($R^2=0.64$) (Figure 10c) and the percent carbonate sand ($R^2=0.66$) (Figure 10d).

**Table 2.** Denudation fluxes, physical erosion fluxes, and chemical weathering fluxes adjusted for precipitation of secondary calcite.

| Name | Latitude | Longitude | Catchment Number | Sampling Date | D (t/km²/yr) | $W_{Total}$* (t/km²/yr) | $W_{carb}$* (t/km²/yr) | $W_{Sil}$ (t/km²/yr) | $E_{Total}$* (t/km²/yr) | $E_{carb}$* (t/km²/yr) | $E_{Sil}$* (t/km²/yr) | Average Annual Runoff (m/yr) | $W_{total}$*/$E_{Total}$* |

D = Denudation flux (physical erosion + chemical weathering); $W_{Total}$ = Total Weathering Flux; $W_{Carb}$* = Adjusted Carbonate Weathering Flux; $W_{Sil}$ = Silicate Weathering Flux; $E_{Total}$* = Total Physical Erosion flux; $E_{Carb}$* = Carbonate Physical Erosion Flux; $E_{Sil}$* = Silicate Physical Erosion Flux.
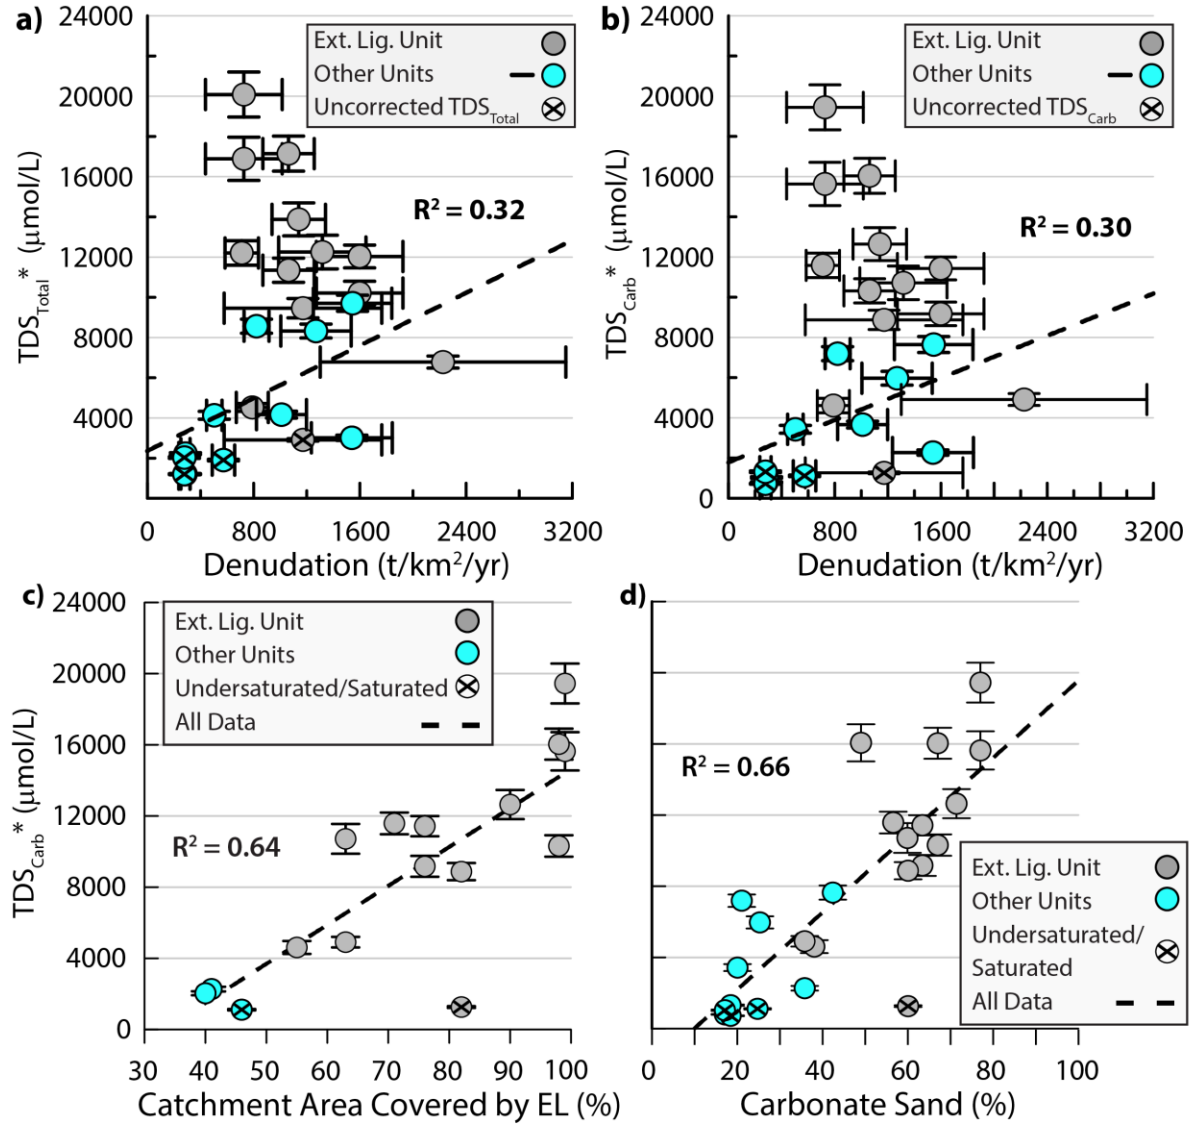

559

**Figure 10**. a) and b) Denudation fluxes plotted against a) $TDS_{Total}*$ and b) $TDS_{Carb}*$. Linear regression applies only to oversaturated non-EL samples. c) and d) $TDS_{Carb}*$ plotted against c) percent catchment area covered by the EL and d) percent carbonate sand. Dashed line reflects linear regression and $R^2$ statistic for the entire dataset. For all panels, samples draining the EL (gray circles) are distinguished from samples draining other lithologic units (cyan circles). No correction to $TDS_{Total}$ or $TDS_{Carb}$ was made for samples overlaid with an "x".

The strongest trends amongst these data are the increase in $TDS_{Carb}*$ with 1) increasing catchment area covered by the EL and 2) with increasing percent carbonate sand. The former trend suggests a strong lithologic control on carbonate weathering rates in the Northern Apennines, where the EL provides higher $TDS_{Carb}*$ concentrations and percent carbonate sand relative to the non-EL lithologies. The correlation between percent carbonate grains and

573    TDS$_{Carb}$* could reflect an increase of precipitated secondary carbonate sand grains with

574    increasing carbonate weathering fluxes. Alternatively, it could reflect erosion of primary

575    carbonates that correlates with weathering. Due to the lack of systematic constraints on the

576    fraction of primary versus secondary grains in the carbonate sand, we are unable to exclude

577    either one of these interpretations. We note, however, that while the fraction of secondary

578    carbonate grains (up to 35%) measured in catchments draining the Marnoso Arenacea Unit

579    (Cavazza, 1993) is substantial, it cannot solely explain the observed increase in carbonate sand

580    grains from 20% to 80% carbonate sand across the entire dataset (Figure 10d).

581

582    These patterns can also be interpreted in the context of the subsurface weathering zone (SWZ),

583    distinct from observations of the exported weathering fluxes derived from river waters. Here, we

584    infer that the EL catchments could reflect a "supply" limit, in that TDS$_{Carb}$* increases with a

585    greater supply of the EL (and presumably therefore higher average bedrock carbonate

586    concentrations across the catchment). We note, however, that the theoretical definition of the

587    supply limit predicts a strong correlation of weathering and denudation and a complete

588    dissolution of all minerals supplied to the weathering zone (West et al., 2005; Gabet and Mudd,

589    2009). Such a limit is unlikely in the EL, as we observe an abundance of primary carbonate in

590    river sands in EL catchments (e.g. Baganza River, Figure S6) and the absence of a correlation

591    between denudation fluxes and TDS$_{Total}$* or TDS$_{Carb}$* (Figure 10a-b). These observations suggest

592    instead that acid availability may ultimately limit weathering in the SWZ. Similarly, weathering

593    for EL catchments also appears to be limited in the river water (i.e. exported weathering fluxes),

594    based on the supersaturation of river waters and the decoupling observed between denudation

595    and metrics of weathering (Figure 5), albeit at a different acid limit than present in the SWZ.

596

597    The interpretation of the controls on weathering limits within the non-EL units is more

598    complicated. The evidence for a supply limit within the SWZ is tenuous, due to the weak

599    correlation between denudation and TDS$_{Total}$* ($R^2$=0.32) or TDS$_{Carb}$* ($R^2$=0.30) (Figure 10) for

600    oversaturated samples. In contrast with the EL Units, however, we observe a moderate, negative

601    correlation between TDS$_{Carb}$* and runoff ($R^2$=-0.58) (Figure 11a) and between TDS$_{Carb}$* and

602    [SO$_4^2$] ($R^2$=0.44). The increase of TDS$_{Carb}$* with decreasing runoff (Figure 11a) suggests that

603    dilution may affect the magnitude of carbonate weathering from non-EL Units. Given the

604    additional negative correlation in the Northern Apennines between runoff and denudation,

605    decreasing dilution with increasing denudation may explain the apparent (albeit weak)

606    correlation between $TDS_{Carb}$* and denudation (Figure 10a-b). For example, we note that all

607    undersaturated samples were collected during the winter/spring season, when runoff is highest,

608    suggesting that dilution may play a role in the concentrations we measure, although we require

609    more systematic sampling of the winter and summer seasons to properly address this point.
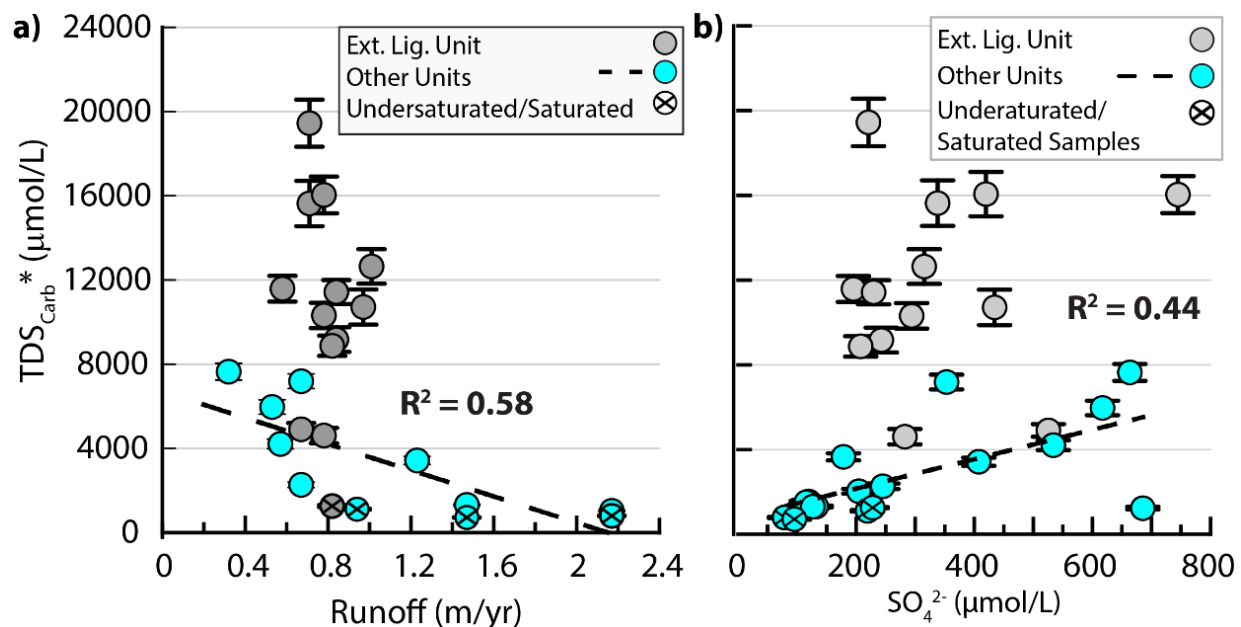

610

611
612    **Figure 11**. a) Runoff plotted against $TDS_{Carb}$* and b) $[SO_4^{2-}]$ plotted against $TDS_{Carb}$*. Linear
613    regressions refer to samples from Other Units (all cyan circles).
614

615    We recognize that denudation fluxes from $[^{10}Be]$ record weathering down to depths of only 60

616    cm (Riebe and Granger, 2013), while the SWZ may in fact be many meters deep (Uhlig et al.,

617    2020). If weathering occurs at depths of greater than a few meters, it is capable of contributing to

618    the overall denudation flux without affecting $[^{10}Be]$. In turn, this may result in an overall

619    underestimation of the measured denudation flux (Riebe and Granger, 2013). Our data support

620    the idea that a substantial portion of the SWZ fluxes likely occurs below 60 cm depth, and thus

621    may not be reflected in the total $^{10}Be$ denudation flux. However, we may further be

622    underestimating the physical erosion flux because $[^{10}Be]$ will only reflect the denudation of

623    primary sand grains formed in the SWZ, whereas the carbonate sand fraction we measured

624    reflects both primary and secondary grains. If a substantial portion of the weathering occurs

625    beneath 60 cm, and then a large portion of this dissolved carbonate is re-precipitated, the total

626   erosion flux at the orogen front will be greater than that estimated by [$^{10}$Be]. To estimate this

627   effect, we quantify the flux of initially weathered carbonate that has been converted back to solid

628   grains (ie, the secondary carbonate erosion flux) for each catchment, by assuming that the

629   difference between [$Ca^{2+}$*] and [$Ca^{2+}$] represents re-precipitation of calcium carbonate (Table

630   S4). These fluxes vary from 0–1,234 t/km$^2$/yr. Astonishingly, for 3 EL catchments, this

631   secondary carbonate erosion flux is higher than the total denudation flux. For all other

632   catchments, the secondary carbonate erosion flux varies from 0–82% of the total denudation

633   flux, with median and average values of 35% and 44%, respectively (Table S4). Though these

634   exact numbers require certainty about the bedrock Sr/Ca and the partition coefficient between

635   dissolved [$Sr^{2+}$] and carbonate Sr/Ca, they illustrate the importance of secondary carbonate

636   precipitation in mixed lithology landscapes.

637

638   Thus far, we have assumed that carbonic acid is the primary weathering agent in the Northern

639   Apennines. Sulfuric acid sourced from the oxidation of sulfide minerals is an important

640   additional source of acidity in a number of mountain ranges (Calmels et al., 2007; Emberson et

641   al., 2016; Blattmann et al., 2019) and a source of dissolved sulfate, $SO_4^{2-}$. The production of

642   sulfuric acid has been observed in a number of caves in northern and central Italy, and has been

643   associated with sulfate reduction of Triassic gypsum/anhydrite deposits (Angeli et al., 2019).

644   This sulfuric acid could surface either through connections between karst springs and river

645   channels (Chiesi et al., 2010) or by faulting (Angeli et al., 2019). Further, minor pyrite in

646   sedimentary units could be a source of sulfuric acid (Cortecci et al., 2008). Quantifying the

647   contribution of sulfuric acid to weathering in the northern Apennines would require constraining

648   evaporite contributions to sulfate using sulfur isotopes. Nevertheless, we propose that sulfuric

649   acid cannot be the dominant control on carbonate weathering in the northern Apennines, given

650   that [$SO_4^{2-}$] are, for the most part, more than an order of magnitude lower than TDS$_{carb}$* (Figure

651   11b). In addition, [$SO_4^{2-}$] are uncorrelated with TDS$_{carb}$* in catchments draining the EL units. In

652   contrast, we observe a moderate correlation between dissolved sulfate and TDS$_{carb}$*, which

653   suggests a potential contribution of sulfuric acid to carbonate weathering in these catchments.

654

655   **5.3.4 Carbonate Weathering and Precipitation Pathways in the Northern Apennines**

656    Here, we summarize the preceding discussion in the context of (1) where carbonate weathering

657    and secondary re-precipitation occur in the landscape, and (2) the limits on carbonate weathering

658    across the landscape (Figure 12). The subsurface is comprised of mixed carbonate-siliciclastic

659    bedrock and the overlying sediment and soil that compose the SWZ. For simplicity, however, we

660    illustrate only the pathways for carbonate sediments in this landscape. Solute compositions in

661    soil waters correspond to the concentrations adjusted for secondary re-precipitation—the

662    weathering zone conditions. In the SWZ, plant respiration (white arrows) produces soil $CO_2$,

663    which interacts with soil water to form carbonic acid (Romero-Mujalli et al., 2018). High $pCO_2$

664    in the soil water (represented by full conical flask symbols) allows a relatively large volume of

665    carbonate to be dissolved in the subsurface, although, based on the presence of primary calcite

666    grains, it is still insufficient to dissolve the abundant supply of carbonate in Northern Apennine

667    rivers (Figure 10b-d).

668

669    The dissolution of carbonate rock produces $HCO_3^-$ and $Ca^{2+}$ ions, which are discharged to rivers

670    (blue arrows). Here, $CO_2$-charged soil water equilibrates with atmospheric $pCO_2$ by degassing

671    excess $CO_2$ (black gradient arrows). This loss of acidity and subsequent pH increase leads to

672    supersaturation of the water with respect to carbonate. Secondary carbonate is thus re-

673    precipitated in the river channel (dashed gray arrows in river channel), particularly along steep

674    sections of the river channel with highly turbulent flow (e.g. waterfalls or catch dams). As a

675    result, the river sediments in the channel are a mix of primary carbonate grains (gray sediment in

676    river channel) and secondary carbonate grains (white sediment in river channel). Given the large

677    initial weathering fluxes and secondary carbonate erosion fluxes that we calculate, it may even

678    be that much of the secondary carbonate precipitation occurs within the SWZ—before entering

679    the river channel—such that there are large dissolution and re-precipitation fluxes within the

680    SWZ. Such fluxes would concentrate Sr/Ca in soil waters and imply that the SWZ has far more

681    dynamic dissolution and re-precipitation fluxes than previously suspected for carbonate-rich

682    landscapes.

683

684    The initial dissolution and subsequent secondary precipitation of carbonate grains results in a

685    decoupling between the limits on the dissolved carbonate flux in soil waters and in river waters.

686    In the SWZ, carbonate weathering is most likely limited by the $pCO_2$ of soils. Between the EL

687    versus non-EL units, differences in acid availability may reflect differences in primary porosity,

688    agricultural practices, or vegetation. We also cannot exclude dilution as a control on carbonate

689    weathering in the non-EL Units, although the pattern of rainfall and snowfall in the Northern

690    Apennines suggests that it may be more important during the winter months. The magnitude and

691    importance of weathering within the SWZ is further illustrated by the ratio of erosion to

692    weathering fluxes (E/W = 4), as reflected in the weathering zones fluxes.

693

694    Once solutes are discharged to streams, the total export of $[Ca^{2+}]$ becomes limited by acid

695    availability in the stream due to equilibration with atmospheric $pCO_2$. Thus, the export of $[Ca^{2+}]$

696    becomes decoupled from the processes in the weathering zone and will instead be limited by the

697    rates of in-stream $CO_2$ degassing and secondary precipitation of calcite, with the ultimate limit

698    being set by the $pCO_2$ in the atmosphere and the quantity of organic matter re-mineralized in

699    river water. The grains and travertine deposits that are newly formed by secondary calcite once

700    again join the physical denudation flux and the export of sediment from mountains. Additional

701    dissolution may occur downstream in floodplains when undersaturated floodplain waters interact

702    with oversaturated mountain streams. Samples collected from mountain streams will reflect the

703    erosion to weathering ratios (E/W = 24) of our exported fluxes. We surmise that upstream

704    reaches of the river could have lower ratios in between those calculated for the SWZ and for

705    exported river fluxes, whereas, at the orogen front, E/W ratios will be even higher, given the

706    importance of secondary carbonate physical erosion in this landscape. Thus, the processes of

707    secondary precipitation and dissolution provide a bridge between physical and chemical erosion

708    of carbonate rock that has to be considered in order to quantify the coupling between mountain
709    uplift and denudation.

710

711

**Figure 12.** Schematic of weathering pathways in the Northern Apennines, illustrating the locations of carbonate weathering and re-precipitation processes in the subsurface and at the surface, respectively. E/W numbers refer to calculated ratios of erosion to weathering at different points on the landscape, dependent upon the degree to which carbonate has been re-precipitated between initial dissolution and export from the mountain front.

717

**6 Conclusions**

In this study, we partition denudation fluxes into physical erosion and chemical weathering fluxes for both carbonates and silicates, in an orogenic setting with mixed siliciclastic-carbonate lithologies. Physical erosion dominates the denudation fluxes, and the proportion of carbonate and silicate in the physical erosion flux is apparently controlled, to first order, by the composition of the bedrock. In contrast, carbonate weathering fluxes dominate the total weathering signal irrespective of the lithology, although the exposure of the External Ligurian Unit in catchments appears to systematically raise carbonate weathering in the weathering zone.

727    Relative to other orogens, the ratio of erosion to total weathering (E/W) is smaller in the
728    Northern Apennines, due to generally higher total weathering fluxes. In the Northern Apennines,
729    carbonate weathering represents an important component of the total weathering flux, and
730    secondary calcite precipitation is ubiquitous. This process converts dissolved riverine solutes
731    back into solid carbonate and, we estimate that 20–90% of $[Ca^{2+}]$ is lost to precipitation of
732    secondary calcite.

733

734    We conclude that the controls on carbonate weathering vary across the landscape. In the
735    weathering zone, carbonate weathering appears to be limited by the partial pressure of $CO_2$ in
736    soils, but the discharge of waters to rivers and the equilibration with atmospheric $pCO_2$
737    fundamentally alter this limit. In rivers, the concentration of dissolved carbonates becomes
738    limited instead by the rates of $CO_2$ degassing and secondary carbonate precipitation. As a
739    consequence, the exported volume of solutes from mountain catchments becomes, at least in
740    part, decoupled from subsurface weathering-zone processes.

741

742    The results from this study advance our understanding of denudational processes in a young
743    mountain range that typifies the initial stages of orogenesis. We have shown that understanding
744    the weathering and erosional processes of carbonate in a thermodynamically limited landscape
745    requires quantifying both the primary processes responsible for carbonate erosion and
746    weathering, as well as the secondary processes responsible for the re-precipitation of carbonates
747    and re-introduction of physical carbonate into the river channels.
