Key Points:

- WaterGAP3 water model data overestimates daily runoff variability in snowmelt influenced watersheds

- Global relationships between mean runoff and daily runoff variability are strongly mediated by snowmelt fraction

- Topographic drivers of mean runoff, snowmelt fraction, and daily runoff variability are best assessed at the mountain range scale

17 **Abstract**

18 Mountain topography alters the phase, amount, and spatial distribution of precipitation. Past

19 efforts focused on how orographic precipitation can alter spatial patterns in mean runoff , with

20 less emphasis on how time-varying runoff statistics may also vary with topography. Given the

21 importance of the magnitude and frequency of runoff events to fluvial erosion, we evaluate

22 whether orographic patterns in mean runoff and daily runoff variability can be constrained using

23 the global WaterGAP3 water model data. Model runoff data is validated against observational

24 data in the contiguous United States, showing agreement with mean runoff in all settings and

25 daily runoff variability in settings where rainfall-runoff predominates. In snowmelt-influenced

26 settings, runoff variability is overestimated by the water model data. Cognizant of these

27 limitations, we use the water model data to develop relationships between mean runoff and daily

28 runoff variability and how these are mediated by snowmelt fraction in mountain topography

29 globally. A global analysis of topographic controls on hydro-climatic variables using a Random

30 Forest Model were ambiguous. Instead, relationships between topography and runoff parameters

31 are better assessed at mountain range scale. Rulesets linking topography to mean runoff and

32 snowmelt fraction are developed for three mid-latitude mountain landscapes—British Columbia,

33 European Alps, and Greater Caucasus. Increasing topographic elevation and relief together leads

34 to higher mean runoff and lower runoff variability due to the increasing contribution of

35 snowmelt. The three sets of empirical relationships developed here serve as the basis for a suite

36 of numerical experiments in our companion manuscript (Part 2).

37

38   **Plain Language Summary**

39   It has long been understood that mountain ranges can have profound influences on the location

40   and intensity of precipitation, for example through the formation of rain shadows. Less clear is

41   how these "orographic effects" are reflected in the details of river runoff, specifically how much

42   runoff varies from day-to-day. Understanding this variability of runoff is important as

43   differences in variability directly influence how rivers respond to changes in rock uplift rate.

44   Here we use results from a global water model integrated with topography data to explore how

45   runoff variability is related to topography in high relief landscapes. Consistent with prior work,

46   we find and expand on the observation that mean runoff and runoff variability are inversely

47   correlated and that the nature of their relation fundamentally depends on how much runoff comes

48   from snowmelt as opposed to rain. In turn, both mean runoff and the importance of snowmelt are

49   positively correlated with aspects of topography. Our results imply that incorporating variability

50   into models of coupled developing orographic patterns in runoff and landscape evolution is

51   critical and we identify a simple framework within which to develop such models. Examples of

52   these models are presented in a companion work (Part 2).

53   **1 Introduction**

54   Weather systems develop over the course of hours to weeks depending on their size (e.g.,

55   Trenberth et al., 2003), while landscapes evolve over millennia and longer. Climatic drivers of

56   the long-term evolution of mountain belts (Whipple, 2009) are impeded by this mismatch in

57   timescale. Modeling weather and hydrology over long timescales is a substantial computational

58   challenge (e.g., Shen et al., 2021), and thus the choices made in representation of the hydro-

59   climate are often baked into the simplified process laws we use to construct landscape evolution

60   models. For fluvial landscapes, the most widely used model for river incision and relief

61 development is the stream power model (Howard, 1994; Whipple & Tucker, 1999). The details

62 of this model have been expounded elsewhere (e.g., see reviews in Kirby & Whipple, 2012;

63 Lague, 2014; Whipple et al., 2022; Whipple & Tucker, 1999; Whittaker, 2012) and we present a

64 more complete synopsis in Part 2. In short the shear stress formulation of stream power asserts

65 that fluvial erosion can be expressed as the product of three terms: a coefficient describing the

66 efficiency of erosion, drainage area raised to an exponent, and local slope raised to another

67 exponent. The latter two terms and the ratio of the exponents can be constrained using

68 topographic data alone (e.g., Wobus et al., 2006), leaving the coefficient of erosion and the value

69 of the slope exponent to account for a large number of important process parameters including

70 climate. While unpacking the assumptions underlying generalized forms of stream power have

71 been addressed by many papers (e.g., Kirby & Whipple, 2012; Lague, 2014; Whipple et al.,

72 2022), we highlight two sets of assumptions of stream power that motivate our analysis of global

73 runoff data. First, it is common to use drainage area as a proxy for discharge. Orographic

74 precipitation (Galewsky, 2009; Roe, 2005) is mimicked in 1D stream power models by adding an

75 additional area dependence on runoff that alters concavity (Roe et al., 2002) and fluvial relief

76 (Roe et al., 2003). In 2D, these basic effects tend to be more ambiguous (Han et al., 2014) and

77 produce discordance between mainstem and tributary morphology (Leonard & Whipple, 2021).

78 Second, simple stream power typically assumes a characteristic discharge, thus entailing either

79 that erosion thresholds are negligible or that the effects of thresholds are subsumed within the

80 stream power parameters itself. This latter possibility has now been carefully examined by

81 changing the temporal scale over which river erosion is modeled (i.e., at the daily scale). By

82 integrating stream power over the probability distribution of flows above erosional thresholds

83 (Lague et al., 2005; Snyder et al., 2003; Tucker, 2004; Tucker & Bras, 2000), the response of

84   river profiles to climate is not only embedded in the coefficient of erosion but also the effective

85   slope exponent (DiBiase & Whipple, 2011; Lague, 2014). While the roles of both orographic

86   precipitation and stochastic climate on stream power have each generated a lot of study on their

87   own, there has been less effort examining them together.

88   Integrating orographic effects with stochastic runoff into stream power models requires

89   better constraints on how mean runoff and runoff variability are related (or unrelated) to each

90   other via topography. Prior studies show that mean runoff and the shape of daily runoff

91   distributions are correlated with each other in rainfall-dominated systems (Molnar et al., 2006;

92   Rossi et al., 2016). Figure 1B illustrates this for contiguous United States using streamflow data

93   from select watersheds where the impact of human disturbance and management has been

94   minimized (Figure 1A). To select watersheds to motivate and validate the global water model

95   data that we use for the majority of this effort (described in greater detail later), we used the

96   Geospatial Attributes of Gages for Evaluating Streamflow (GAGES-II) reference gauges and the

97   Hydro-Climatic Data Network (HCDN-2009). HCDN-2009 is a subset of GAGES-II and thus

98   includes a smaller number of sites. Details for selection of those stations used for validation are

99   described below along with how we derived the shape parameters of each distribution. However,

100   note here that higher shape parameters shown in Figure 1 indicate lower runoff variability. The

101   empirical data split into two broad relationships. Separation of the two trends appears to

102   correspond to mean annual temperatures of around 0-10° C (Figure 1B), which we hypothesize is

103   due to relatively small changes in the fraction of mean annual streamflow that is derived from

104   snowmelt. While prior work has examined how orographic patterns in the spatial distribution of

105   snow alters stream power predictions (Anders et al., 2008), we are not aware of any studies

106   showing how snowmelt alters stochastic runoff and stream power predictions. As such, coupled

107   models of climate and tectonics using stream power (e.g., Beaumont et al., 1992; Willett, 1999)

108   may be missing important feedbacks between topographic relief and snowmelt as mountain

109   ranges grow.

110   The lack of focus on integrating orographic precipitation and stochastic runoff into

111   stream power models is likely due to data limitations and the dearth of simple hydrological

112   relations that can be upscaled to landscape evolution timescales. Precipitation observations

113   provide a starting point, though simplifying water inputs into streamflow outputs are riddled with

114   nonlinearities that can be hard to generalize. Rainfall runoff is nonlinear due to scaling properties

115   within watersheds and dynamical nonlinearities in hillslope runoff generation (e.g., Sivapalan et

116   al., 2002). Furthermore, the relative contribution of different runoff generation mechanisms (i.e.,

117   extreme precipitation, soil moisture excess, snowmelt) to flood frequency is only beginning to be

118   characterized under modern climate conditions (e.g., Berghuijs et al., 2019), let alone for time-

119   varying ones. Process-based hydrological models help unpack these nonlinearities for a given

120   setting (Fatichi et al., 2016), but are typically applied at small spatial scales. Our approach is to

121   use a global water model (Alcamo et al., 2003; Döll et al., 2003) to help constrain how

122   topography, runoff generation, and streamflow statistics can be generalized for river incision

123   modeling more broadly.

124   **2 Background**

125   2.1 Orographic effects

126   Topography perturbs the equilibrium structure of the atmosphere by adding roughness,

127   obstructing air masses, and serving as a heat source (Smith, 1979). The conventional treatment of

128   orographic precipitation in landscape evolution studies (e.g., Beaumont et al., 1992; Willett,

129 1999) focuses on the thermodynamic implications of mountain topography on how precipitation

130 is extracted from the atmosphere via forced ascent. The saturation vapor pressure of water in air

131 is related to its temperature via the Clausius-Clapeyron equation (see review in Roe, 2005). As

132 air masses move up and over mountain topography, precipitation on windward slopes increases

133 as partially saturated air cools during ascent. A 'rain shadow' subsequently develops when the

134 relatively drier air descends and warms on leeward slopes. This first-order description is well-

135 rooted in atmospheric physics and observations (Barros & Lettenmaier, 1994). To extend these

136 dynamics to air parcels flowing over more complex terrain, Smith & Barstad (2004) developed a

137 linear model of orographic precipitation that accounts for atmospheric dynamics, upwind

138 advection, and downslope evaporation. In this context, linearity does not refer to a single

139 function describing rainfall but is instead a property of the system of differential equations used

140 such that they are analytically tractable. Because settling velocities of snow are an order of

141 magnitude lower than rain, this model can be used to examine how snow alters the spatial

142 distribution of water inputs (Anders et al., 2008). However, one notable limitation to the linear

143 model of orographic precipitation is that it does not account for the blocking of air by terrain, a

144 nonlinear process that depends on the Brunt-Vaisala frequency describing the horizontal

145 propagation of waves, horizontal windspeed, and orogen-scale relief (Barros & Lettenmaier,

146 1994; Galewsky, 2009; Jiang, 2003). Given that one of the key targets of landscape evolution

147 models is to couple topography to climate through time, linear models of orographic

148 precipitation are perhaps best suited to smaller mountain ranges.

149   Another approach towards characterizing orographic precipitation is to use climatological

150 observations, especially since the advent of satellite-based remote sensing. For example, the

151 Tropical Rainfall Measuring Mission (TRMM) was spaceborne for 17 years and provided new

152   insights into complex spatial patterns in rainfall set up by high topography (e.g., Bookhagen &

153   Burbank, 2006; Bookhagen & Strecker, 2008; Deal et al., 2017; Forte et al., 2016; Nesbitt &

154   Anders, 2009). One of the key insights from these studies is the central importance of local relief

155   to driving spatial patterns in rainfall. For example, in the Himalaya, TRMM rainfall revealed two

156   narrow bands of rainfall that correspond to abrupt physiographic transitions into the Lesser

157   Himalaya and into the Greater Himalaya which had not been previously identified (Bookhagen

158   & Burbank, 2006, 2010). As such, spatial patterns derived from TRMM rainfall are increasingly

159   being used to inform interpretations of river channel profiles (Adams et al., 2020; Bookhagen &

160   Strecker, 2011; Leonard et al., 2023), though these approaches typically assume mean rainfall is

161   directly proportional mean runoff. While other remote sensing products like MODIS can also

162   help constrain snow cover to construct a full water budget (Bookhagen & Burbank, 2010), such

163   products tend to require temperature-index or process-based hydrological models to reliably

164   estimate snowmelt contributions to streamflow (Walter et al., 2005).

165   Given the importance of snowmelt to streamflow in mid-latitude mountain ranges

166   (Barnett et al., 2005; Barnhart et al., 2016), the difficulty of obtaining direct estimates of

167   snowmelt leads to substantial uncertainty when using remotely sensed rainfall data as a proxy for

168   runoff. Altering the phase of precipitation can cause up to 100% reductions in snowmelt

169   contributions to streamflow in settings near the freezing temperature window (Adam et al.,

170   2009). This has prompted some authors to suggest that climate change driven reductions in

171   snowmelt fraction generally leads to lower streamflow as snowfall gives way to rain (Berghuijs

172   et al., 2014). Such arguments rest on the premise that snowmelt runoff will lead to higher runoff

173   ratios, all other things being equal, because solid water is stored in the snowpack and released

174   more slowly than rainfall runoff. Better understanding of orographic effects on the snowmelt

175   contribution to streamflow in mountain landscapes is sorely needed to improve stream power

176   models of river incision.

177   2.2 Stochastic river incision

178   Early efforts to integrate stochastic hydrology into stream power models of river incision

179   (Snyder et al., 2003; Tucker, 2004; Tucker & Bras, 2000) were based on the pioneering work of

180   Eagleson (1978). By simulating rainfall events as Poisson distributions of intensities, durations,

181   and inter-storm periods, rainfall events were represented as rectangular pulses that can be

182   converted to runoff and routed across the landscape in order to evaluate the impact erosion

183   thresholds on landscape evolution. Complementary efforts by Lague et al. (2005) chose to

184   simulate streamflow directly at the daily time step using the stochastic 'precipiton' model. This

185   model considers the time travel distribution of quanta of precipitation that produces runoff and

186   generates daily streamflow distributions that follow an inverse gamma distribution (Crave &

187   Davy, 2001).

188   Despite the differences in the hydrologic assumptions made by these early modeling

189   efforts, together they highlighted the need for adding stochastic events to stream power in order

190   to interpret the long-term evolution of river profiles. Under this view, the steady state form of

191   river profiles was no longer a simple function of mean climate, but instead reflected the complex

192   interplay between the frequency of large flows and erosional thresholds set by coarse sediment

193   (Shobe et al., 2016) and the detachment of bedrock (Whipple et al., 2000). While the overall

194   approach of these efforts was similar, the functional form of probability distributions of

195   streamflow differed. The use of daily data, while insufficient for short-duration flash floods,

196   balances important tradeoffs in characterizing magnitude-frequency relationships while also

197   being tractable to simulate over landscape evolution timescales. Poisson rectangular pulses

198   always generate light-tailed, exponential, daily runoff distributions while the inverse gamma

199   distribution is able to produce heavy-tailed distributions that do not have a finite variance,

200   depending on the value of shape parameter. There is still an open question as to how heavy-tailed

201   streamflow distributions truly are (Malamud & Turcotte, 2006; Molnar et al., 2006), though the

202   advantage of adopting these stochastic frameworks is that they are well-suited to simulating both

203   frequent and infrequent flows and thus determining the geomorphically effective event (Huang &

204   Niemann, 2006). Rossi et al. (2016) recently suggested that the stretched exponential, or

205   Weibull, distribution provides a flexible probability distribution that spans light-tailed to

206   apparently heavy-tailed distributions (Laherrère & Sornette, 1998), and thus is what we choose

207   to fit observed and model runoff daily runoff data below.

208   Regardless of how stochastic processes are represented, these early efforts prompted a

209   large number of studies to take a closer look at whether relationships between long-term erosion

210   rates and river morphology can be better explained using stochastic-threshold models of river

211   incision (Campforts et al., 2020; Desormeaux et al., 2022; DiBiase & Whipple, 2011; Forte et al.,

212   2022; Scherler et al., 2017). While success is decidedly mixed, the general outcome of using

213   stochastic-threshold models has been to provide an alternative interpretation to nonlinear

214   relationships between river channel morphology and long-term erosion rates (Harel et al., 2016;

215   Marder & Gallen, 2023). In these cases, nonlinear relationships between river morphology and

216   long-term erosion rates arise because erosional thresholds are exceeded more frequently as

217   erosion rate and relief increase. The climate driver on river profile evolution is not mean annual

218   precipitation itself, but how the soil water balance (Deal et al., 2018) and the hydrologic structure

219   of watersheds (Basso et al., 2023) mediate flood frequency. These concepts place the central

220   focus on water storage-discharge relationships (Botter et al., 2009; Kirchner, 2009) to condition

221   how rainfall events are converted to runoff ones. The same kind of framework can be used to

222   account for seasonal snowmelt contributions to streamflow (Schaefli et al., 2013).

223   **3 Datasets**

224   Our overarching goal is to better parameterize 1D models of fluvial profile evolution that

225   account for both stochastic events and orographic controls on runoff generation. Model

226   development is the focus of our companion manuscript (Forte & Rossi, 2023). The focus of this

227   manuscript is on developing empirical relationships between topography and daily runoff

228   statistics in mountain settings. Note that runoff and streamflow, i.e., discharge, are not

229   synonymous terms. For empirical data, streamflow data are typically what is measured and

230   runoff is inferred by normalizing the data by drainage area. For water model data, runoffs are

231   simulated directly. We primarily rely on three datasets: (1) a daily, global water model derived

232   from climate reanalysis data (WaterGAP3 data including daily runoff), (2) observational stream

233   gauge data from the contiguous United States (HCDN-2009 daily streamflow), and (3) near

234   global topographic data (SRTM-90 and derived HydroSHEDS v1 gridded elevation).

235

236   3.1 Hydrology Data

237   Because streamflow data availability and quality is globally variable, we sought a single

238   global runoff dataset that could be used to interrogate modern relationships among topography,

239   snowmelt, and runoff. We used the Water Global Assessment and Prognosis (WaterGAP3), the

240   most recent version of a 20+ year old global water model (Alcamo et al., 2003; Döll et al., 2003).

241   WaterGAP3 improves on prior versions by increasing the spatial resolution from the original

242   0.5° to 0.25° pixel size (Eisner, 2015) and is one model included in the Earth2Observe Water

243 Resource Reanalysis project (Schellekens et al., 2017). These model data have broad utility (e.g.,

244 Schmied et al., 2014), including for parameterization of stochastic-threshold incision models

245 (STIM) of river incision (Campforts et al., 2020). For this analysis, we downloaded the global,

246 20-year, daily time series from the Earth2Observe portal (www.earth2observe.eu; last accessed

247 April 8, 2022) spanning from January 1, 1980 to December 31, 1999. Daily data represent the

248 mean value of each variable for each day.

249   For each pixel and day, WaterGAP3 contains a large number of input and derived hydro-

250 climatological parameters including precipitation, runoff, discharge, and evapotranspiration. We

251 primarily focus on the derived runoff variables from WaterGAP3, but also briefly consider

252 temperature and precipitation. Daily average surface temperature is not distributed with

253 WaterGAP3, so we rely on another reanalysis product of identical resolution from the

254 Earth2Observe set, namely SURFEX-TRIP (Decharme et al., 2010, 2013). Surface temperature

255 data are used to help interpret variation we see within the WaterGAP3 runoff data. Runoff data

256 are subdivided into three components in WaterGAP3: surface runoff (R_s), subsurface runoff

257 (R_{sb}), and snowmelt *(R_{sm})*, where total daily runoff (R_t) is the sum of the three. In the original

258 WaterGAP3 dataset, all of these components of runoff are denoted with the variable '*Q*'. We do

259 not use this notation here given the common association of Q with discharge [L^3/t] as opposed to

260 runoff [L/t]. For each pixel across the time-series, we calculated mean daily runoff ($\bar{R}_t$), mean

261 daily precipitation ($\bar{P}$), means of each of the three runoff components ($\bar{R}_s$, $\bar{R}_{sb}$, $\bar{R}_{sm}$), and

262 Weibull shape (*c*) and scale (R_0) parameters of the daily total runoff distributions (see section 4.1

263 for details). Given our interest in probing the importance of snowmelt, we also calculated the

264 fraction of runoff contributed by snowmelt (SF), where:

265

266
$$SF = \frac{\overline{R_{sm}}}{\overline{R_t}} \tag{1}$$

267

268   Similarly, we calculate baseflow fraction of runoff (BF), where:

269
$$BF = \frac{\overline{R_{sb}}}{\overline{R_t}} \tag{2}$$

270   that we use to exclude watersheds with a substantial groundwater component to its daily fluxes.

271   To validate model runoff data, we used observational streamflow data from the Hydro-

272   Climatic Data Network – 2009 (HCDN-2009) (Lins, 2012). These 743 stream gauges were

273   identified by the USGS to be high quality, long, continuous records for watersheds with minimal

274   impact by humans (e.g., due to landcover change, dams, and diversions). We downloaded

275   streamflow data from the National Water Information System (NWIS) server for the dates

276   between January 1, 1980 and December 31, 1999, to directly compare to the WaterGAP3 data.

277   During the processing of individual HCDN-2009 time series data, any day that included

278   provisional data or data where there was an extra qualifier on the quality (e.g., 'ICE') was

279   removed and treated as NaN data. We characterize the completeness of the time series by

280   dividing the number of days with reliable data by the total number of days. Because HCDN-2009

281   stream gauges are a subset of the reference stations in the Gages for Evaluating Streamflow

282   version II (GAGES-II) network, we were able to use watershed boundaries provided by Falcone

283   et al. (2011) to calculate watershed-averaged properties and normalize streamflow by drainage

284   area. This latter calculation was used as an estimate for daily runoff. Processing and validation of

285   the WaterGAP3 runoff model against HCDN-2009 observations is described in section 4.2.

286   3.2. Topography Data

287   Because we are focused on how hydroclimatic parameters vary with topography in

288 mountain settings, it is necessary to pair the WaterGAP3 data with a global topographic dataset.

289 We largely used the HydroSheds v1, 15-arcsecond, digital elevation model that is derived from

290 SRTM elevation data (Lehner et al., 2008). We also used the higher resolution SRTM-90 data

291 (Farr et al., 2007) for watershed delineation when validating WaterGAP3 against HCDN-2009

292 data. The HydroSheds v1 topographic data are used for two purposes: (1) To screen for portions

293 of the global surface where orographic feedbacks with climate are relevant, and (2) To develop

294 empirical relationships between topography and runoff statistics. With respect to data screening,

295 we only used WaterGAP3 data where the mean elevations are greater than 250 meters above sea

296 level and where local reliefs are greater than 500 meters. To calculate local relief at a fixed scale,

297 we first reprojected the global geographic DEM into an equal area cylindrical projection and then

298 calculated local relief within a 2.5 km radius circular moving window. This is a scale that prior

299 studies have shown to linearly correlate with river channel steepness (e.g., DiBiase et al., 2010),

300 and thus expect it to be well suited to developing empirical relationships between river

301 morphology and local relief. After the relief calculation, we projected the data back into the

302 original WGS 84 geographic coordinate system to facilitate calculation and comparisons with the

303 rest of the datasets that were also in geographic coordinate systems. The initial screening of the

304 WaterGAP3 data using local relief is then further filtered to exclude pixels where baseflow (eq.

305 2) exceeds 0.25, with an eye towards minimizing the confounding factor of large groundwater

306 contributions. To develop relationships between topography and runoff statistics we record

307 minimum, mean, and maximum elevations within a WaterGAP3 pixel and the mean local relief

308   within a WaterGAP3 pixel as calculated from the enclosed 60 HydroSheds pixels (i.e., there are

309   60 HydroShed pixels within each WaterGAP3 pixel).

310   **4 Data Analysis**

311   To develop empirical relationships between topography and runoff statistics from

312   WaterGAP3, it was first important to figure out at which scale such relationships might emerge.

313   To this end, we conduct both a global analysis and a set of regional ones that broadly correspond

314   to the mountain range scale. These empirical relationships serve as the basis for the model

315   development and analysis we conduct in Part 2 (Forte & Rossi, 2023). There are four main steps

316   to the data analysis: (1) Characterization of statistical parameters for daily runoff; (2) Validation

317   of WaterGAP3 model derived parameters with HCDN-2009 stream gage observations; (3)

318   Global assessment of topographic controls on runoff, runoff variability, and snowmelt fraction,

319   and (4) Development of regionally-based relationships between topographic metrics and runoff

320   statistics.

321   4.1. Daily Distributions

322   A number of probability distributions have been considered for the problem of bedrock

323   river incision, including exponential (Snyder et al., 2003; Tucker, 2004), power law (Molnar et

324   al., 2006), inverse gamma (Campforts et al., 2020; DiBiase & Whipple, 2011; Lague et al., 2005;

325   Scherler et al., 2017) and Weibull (Forte et al., 2022; Rossi et al., 2016) distributions. We follow

326   Rossi et al., (2016) and use a two-parameter Weibull distribution to fit the right tail of the daily

327   runoff distribution above a threshold value. Choosing thresholds to fit empirical distributions is a

328   notoriously vexing challenge (e.g., Dupuis, 1998) and makes it more challenging to implement in

329   numerical models (see Forte & Rossi, 2023), though it enables better fidelity to the observed

330 right tail. For this analysis, the threshold is treated as a third parameter that is held constant

331 across sites to enable comparison of fit parameters. Above the threshold, distributions are

332 described by a shape parameter (c_x) that describes daily variability and a scale (x_0) parameter

333 related to the mean of the distribution, where:

$$pdf(x; x_0, c_x) = \frac{c_x}{x_0}\left(\frac{x}{x_0}\right)^{c_x-1} exp^{-1(x/x_0)^{c_x}} \tag{3}$$

335 Because we are only fitting the right tail of the distribution, the parametric mean and the

336 empirical mean need not match. The mismatch between the two is a measure of how well tail

337 fitting is able to represent the full distribution. We use the fit parameters to characterize both

338 daily precipitation (p_0, c_p) and daily runoff (r_0, c_r). Interpretations of fit parameters primarily

339 focus on the shape parameter because it describes the right tail of daily values, which we

340 colloquially refer to as the variability. Larger values of c_x indicate lower variability (i.e., smaller

341 relative differences between daily runoff values), where $c_x=1$ is equivalent to the exponential

342 distribution. The need for three parameters and the inability to analytically integrate the product

343 of this distribution with stream power is not ideal, posing important challenges to numerical

344 simulations of bedrock rivers (Forte & Rossi, 2023).

345   To estimate shape parameters, we follow Wilson & Toumi (2005) and perform a linear fit

346 on the natural log linearized right tail of the exceedance frequency distribution above a threshold.

347 On the transformed data, the shape parameter, c_x, is the slope of the regression, and the scale

348 parameter, x_0, is exp(-intercept/slope) of the regression. Because parametric fits will be sensitive

349 to threshold choice, distribution parameters were calculated using two thresholds for the daily

350 runoff data, the upper 5% and upper 1% of daily values. These thresholds reflect a compromise

351 between fitting the majority of flows while also honoring the right tail, the latter of which

352   dictates the nonlinear relationship between channel steepness and long-term erosion rates.

353   Figures and discussion are based on the 1% threshold for both runoff and precipitation

354   distributions. This corresponds to the event magnitude that happens 3-4 times per year. While

355   threshold choice did alter the best-fit values for c_r, suggesting that a simple Weibull distribution

356   is not able to fully characterize all cases, this variation in c_r did not substantially alter the relative

357   spatial patterns in the shape of the right tail. Runoff parameters were calculated on both the daily

358   streamflow data (HCDN-2009) and the daily total runoff data from WaterGAP3. Pixel-based

359   values in WaterGAP3 are not directly comparable to the watershed-averaged ones in HCDN-

360   2009. In the following section, we address this challenge in the context of validating water model

361   runoff data against observations.

362   4.2. Runoff Parameter Validation

363   Prior validation of WaterGAP3 data suggests that model data robustly reproduce mean

364   river discharge from gauging stations (Beck et al., 2017; Eisner, 2015; Schmied et al., 2014,

365   2020). None of these prior assessments considered how well daily runoff variability is

366   represented. Given the importance of daily runoff variability to bedrock river incision modeling,

367   it is thus important to assess the extent to which shape parameters calculated from WaterGAP3

368   are consistent with those observed at stream gauges. For the sake of comparison, we first

369   screened the HCDN-2009 network using the same topographic criteria used to screen

370   WaterGAP3. Namely, we excluded watersheds where catchment relief (i.e., maximum minus

371   minimum elevation within the catchment) is less than 500 meters and where mean elevation is

372   less than 250 meters. Of the retained sites, we also imposed the additional criterion that HCDN-

373   2009 daily runoff records are >95% complete within the WaterGAP3 time period (January 1,

374   1980 - December 31, 1999). We also removed data that occurs on leap days because these days

375   are not calculated in the WaterGAP3 time series.

376   Once candidate HCDN-2009 stations were identified for validation, we needed to process

377   the WaterGAP3 data to enable fair comparison. The first approach uses the mean runoff and

378   runoff variability parameters calculated for each pixel in WaterGAP3. By oversampling these

379   raster datasets of stochastic parameters to 1.5 seconds per pixel, HCDN-2009 watershed

380   boundaries were used to calculate spatially averaged values of runoff parameters. While this

381   treatment may be valid for small HCDN-2009 watersheds of similar scale to the WaterGAP3

382   pixels, this calculation may be problematic for larger watersheds where runoff should be routed

383   downstream. As such, the second approach uses watershed boundaries to clip and route the

384   WaterGAP3 data for each day within the 20-year time series. The mean runoff and shape

385   parameter of the routed data are then calculated for the daily, routed data at the river outlet. For

386   this computationally intensive approach, we used TopoToolbox (Schwanghart & Scherler, 2014)

387   to: (1) acquire SRTM-90 digital elevation models (DEMs) for each watershed via the

388   OpenTopography API, (2) project each DEM to the Universal Transverse Mercator (UTM)

389   projection, (3) clip each day of the WaterGAP3 data to the watershed boundary and resample to

390   the resolution of the DEM, (4) route discharge through the basin to build a time series of daily

391   runoff at the outlet of each watershed, and (5) calculate mean runoff and shape parameters for

392   the outlet time series.

393   4.3. Global Analysis

394   After understanding the strengths and limitations of WaterGAP3, these model data were

395   used to identify the strongest predictors of mean runoff and daily runoff variability globally. The

396   global analysis used two complementary approaches: (1) Develop relationships between mean

18

397 runoff and variability (e.g., Molnar et al., 2006; Rossi et al., 2016), in a way that can account for

398 the potential influence of snowmelt, and (2) Use unsupervised machine learning to probe the

399 WaterGAP3 data and help identify strong predictors of mean runoff, snowmelt, and runoff

400 variability.

401 For the first approach, we used the snowmelt fraction (Eq. 1) to partition the filtered

402 WaterGAP3 data (see Section 3.1) into bins. Within each bin, we fit both a linear and a power

403 law function relating mean runoff and the shape parameters of each pixel within that bin. This

404 approach was motivated by empirical (Rossi et al., 2016) and ecohydrological modeling (Deal et

405 al., 2018) studies that show how climatically driven gradients in daily runoff variability differ

406 between rainfall-runoff and snowmelt-runoff regimes. For example, Rossi et al. (2016) showed

407 that watersheds with lower snowmelt contributions were better described by a power law

408 relationship between mean runoff and its associated Weibull shape parameter. In contrast,

409 regions with higher snowmelt contributions showed a more linear relationship between these

410 parameters. To compare the fits of both functions, we consider both the RMSE and the reduced

411 chi-squared statistic under the view that that minimization of RMSE and/or reducing the chi-

412 squared statistic closer to one should indicate the 'better' fit to the data.

413 In the second approach, we consider a larger suite of hydro-climatological, topographic,

414 and geographic variables. Random forest regression (RFR) was used to assess the relative

415 importance of potential predictor variables with respect to a given 'target' variable (Grömping,

416 2009). Target variables are hydro-climatic ones chosen based on their potential relevance to

417 relationship between mean runoff and runoff variability (i.e., mean temperature, mean

418 precipitation, mean runoff, daily runoff variability, and snowmelt fraction). The list of predictor

419 variables are broader and varied according to each target. Predictor variables included

420   topographic (mean elevation, maximum elevation, mean local relief), geographic (latitude), and

421   hydro-climatic (mean temperature, mean precipitation, daily precipitation variability, mean

422   runoff, daily runoff variability, and snowmelt fraction) variables. We also attempted to thin

423   predictor variables and remove what amounts to duplicates, e.g., as described in the results,

424   latitude is the primary predictor of mean annual temperature and thus for other RFRs, we only

425   include MAT as opposed to both MAT and latitude. Ultimately, we are not interested in the

426   prediction per se, but to use the RFR to help identify which variables emerge as the most viable

427   candidates linking mean runoff, snowmelt fraction, and daily runoff variability. In particular, we

428   sought to discover which and whether any of the topographic metrics can be used to generalize

429   hydro-climatic relationships that may co-evolve with growing topography. To perform the RFR,

430   we used the *RandomForestRegressor* within *SciKit-Learn*, using the default values and a seed for

431   the random state of 0.

432   4.4. Regional Cases

433   As we discuss in the context of our findings below, the global analysis revealed that

434   generalizable relationships between topography and hydro-climatology were difficult to isolate at

435   this largest spatial scale. While the global analysis reinforced the notion that snowmelt fraction

436   mediates the relationship between mean runoff and daily runoff variability, scatter in these

437   relationships clearly reflect the geographic diversity of montane hydrology. Furthermore, the

438   lack of unambiguous topographic predictors that could be used to build rules for co-evolving

439   stochastic parameters with the growth of mountain ranges limits the utility of the results from the

440   global analysis to the application of 1D bedrock river incision modeling (Forte & Rossi, 2023).

441   As such, we identified relationships between topography and stochastic runoff specific to

442   individual mountain ranges, where differences in regional climate and geography can be partially

443   accounted for. To begin this regional analysis, we started at first at the global scale and used a 2°

444   rectangular moving window to calculate the Spearman's rank correlation coefficient between

445   candidate topographic variables and hydro-climatological ones. The topographic variables

446   considered were the same as in the global analysis (mean elevation, maximum elevation, and

447   mean local relief). The hydroclimatic variables we focused on were mean runoff and snowmelt

448   fraction, the latter of which can be linked to daily runoff variability using relationships from the

449   global analysis. We opt to focus on snowmelt fraction instead of daily runoff variability directly

450   because one of the hypotheses we are trying to test in the 1D river incision modeling (Forte &

451   Rossi, 2023) is how and whether snowmelt dynamics alter interpretations of stream power based

452   analyses of river profiles. The results of the rank correlation analysis were used as the basis of

453   selecting three regions where well-defined relationships can be developed between topography

454   and hydro-climate. Specifically, these regional cases focus on the mid-latitude mountains of

455   British Columbia, European Alps, and the Greater Caucasus (Figure 2), where snowmelt

456   contributes a sizable fraction of daily streamflow.

457   **5 Results**

458   5.1 Validation of WaterGAP3

459   Figure 3 summarizes the results from our validation of WaterGAP3 model data against

460   historical observations from select HCDN-2009 stream gages. The mean values for both datasets

461   plot around the 1:1 line without obvious bias (Figure 3A), lending support to prior assessments

462   (e.g., Beck et al., 2017; Eisner, 2015; Schmied et al., 2014, 2020). However, scatter around this

463   relationship shows that a >25% mismatch in mean values is not unusual. In general, simple

464   spatial averaging (closed symbols) performs almost as well as the computationally intensive

465   routed approach (open symbols), though routing matters for individual cases. From this, we

466   conclude that the HCDN-2009 watersheds are at the appropriate scale for WaterGAP3 validation

467   and that downstream scaling of streamflow statistics is not strongly influencing our parameter

468   estimates. This perhaps not surprising given that the filtered set of HCDN-2009 watersheds used

469   are relatively small (interquartile range of 105-542 km^2), well within the average pixel size of the

470   WaterGAP3 data and typically smaller than the mountain range scale. For lower values of the

471   shape parameter (i.e., higher runoff variability), the correspondence between the observations

472   and the water model is acceptable (Figure 3B). However, for most watersheds, the shape

473   parameters from WaterGAP3 are less than their empirical counterparts (Figure 3B; D) except at

474   higher shape parameters (i.e., lower daily runoff variability). In these cases, WaterGAP3 values

475   are systematically lower than the HCDN-2009 gage data. This implies that WaterGAP3 tends to

476   *overestimate* variability for these watersheds. For the lower variability watersheds, the routed

477   version of WaterGAP3 does slightly improve water model performance (Figure 3B), but does not

478   remove the systematic bias. The residuals of the mismatch between the HCDN-2009 and

479   WaterGAP3 values do not reveal a relationship between the mean and variability (Figure 3C),

480   which might occur if the WaterGAP3 model was systematically altering storage-release

481   relationships in hydrographs (e.g., due to limitations in how hydrologic processes are represented

482   in the model). However, comparison of the residuals of the shape parameter to the mean annual

483   temperature each the watershed (Figure 3D) indicates one possible interpretation for why

484   variability in lower variability watersheds is overestimated in the WaterGAP3 data. The majority

485   of lower variability basins tend to occur in colder settings, suggesting the possibility that

486   snowmelt processes are not being adequately represented in the WaterGAP3 data. This result

487   supports the argument that WaterGAP3 could benefit from improving the partitioning of runoff

488   into fast and slow components (Eisner, 2015). The direction of the mismatch is consistent with

489   the notion that snow storage and release may not be fully resolved in WaterGAP3 data even

490   though mean runoff is well represented in the water model.

491   While systematic differences between model and empirical estimates of daily runoff

492   variability is an important limitation to consider, we continue to use WaterGAP3 as our base

493   dataset for a few reasons: (1) It is globally uniform, allowing for comparison of stochastic runoff

494   in diverse settings, and (2) The systematic bias in variability has been quantified so that its

495   effects can be considered. Importantly, the bias in WaterGAP3 estimates of daily runoff

496   variability lead to a *conservative* estimate of the dynamics we are examining in our 1D modeling

497   of bedrock river incision (Forte & Rossi, 2023). Because hypothesized orographic feedbacks

498   induce lower runoff variability as a mountain range grows, thereby increasing the degree of

499   nonlinearity between channel steepness and erosion rate, it is preferable for the underlying rules

500   setting these feedbacks to overestimate variability than the alternative.

501   5.2 Global relationships (relating mean and variability)

502   Figures 4-5 summarize the results for how the parametric fit parameters relate to mean

503   runoff after binning the data by snowmelt fraction. Across all bins, WaterGAP3 data show that

504   mean runoffs are inversely related to daily runoff variabilities, consistent with prior studies (e.g.,

505   Molnar et al., 2006; Rossi et al., 2016). The large gridded WaterGAP3 dataset allowed us to

506   more systematically explore these relationships at relatively fine (5%) intervals of snowmelt

507   fraction (Figure 4). Each subpanel in Figure 4 is a heatmap showing the density of WaterGAP3

508   observations of how the best-fit shape parameters relate to the empirical mean. Regressions on

509   the pixel-level data are shown (solid lines show the better fit between linear and power law

510   regressions). HCDN-2009 observational data are also shown as points for reference. Figure 4

511   demonstrates that it would be difficult to constrain these relationships using observational data

512   alone because representation of different snowmelt fractions can be sparse, especially at higher

513   snowmelt fractions. More importantly, it shows that the functional form of the relationship

514   between the mean and variability changes from sublinear to linear with increasing snowmelt

515   fraction. Using Figure 4 as our guide, we identified a snowmelt fraction of 0.35 as the transition

516   where sublinear relationships give way to linear relationships. Note that this transition is higher

517   than the 10% snowmelt threshold used to delineate snowmelt from rainfall-runoff dominated

518   watersheds in Rossi et al. (2016). This disparity likely arises from two factors. First, that prior

519   analysis focused on the snow fraction of precipitation and not the snowmelt fraction of runoff.

520   Second, the sparsity of observations at higher snowmelt fractions in the HCDN-2009 data are not

521   sufficient to define such a threshold.

522   To more succinctly summarize these findings, Figure 5A-B shows the same plots by

523   binning the data above and below a threshold snowmelt fraction of 0.35. The best of the

524   regression lines from Figure 4 are also plotted for reference. Figure 5A-B highlights that

525   individual regressions largely cluster around each other, especially in the domain where they are

526   well constrained by data. It also shows that the relative spread of parameter values is smaller

527   when there is a high fraction of snowmelt. The linear relationships shown at higher snowmelt

528   fractions (Figure 5B) are strongly underestimating the value of the shape parameter as estimated

529   from gaged basins, consistent with validation results (Figure 3B). However, empirical

530   observations still suggest a linear relationship between the empirical mean runoff and the shape

531   of the daily runoff distribution at higher snowmelt fractions.

532   Because empirical means are not equivalent to the mean value implied by parametric fits,

533   Figure S1 reports the mismatch between the scale parameter fit to the data (i.e., above the 1%

534   threshold or ~4 largest floods per year) and the scale parameter implied by the empirical mean.

535   These results are summarized in Figure 5C-D. In general, the parametric fits produce scale

536   parameters that are on par with the empirical means only at low snowmelt fractions. At higher

537   snowmelt fractions, the parametric fits have much higher scale parameters than the empirical

538   mean would imply, thereby suggesting that the Weibull distribution is not doing a good job at

539   describing the full distribution of events. Finding a single distribution to describe empirical data

540   is a well-known problem and poses unique challenges to simulating runoff distributions over

541   landscape evolution timescales, a challenge we tackle in part 2 of this analysis (Forte & Rossi,

542   2023). Nevertheless, by treating all the data in the same way, we show that the functional

543   relationship between daily runoff variability and mean runoff is highly sublinear at low

544   snowmelt fractions, much like shown in previous studies (Molnar et al., 2006; Rossi et al., 2016).

545   At high snowmelt fraction, the relationship becomes more linear, albeit with the caveat that the

546   form of the distribution may also be changing. Our estimates of this transition using WaterGAP3

547   data provide conservative estimates of orographic feedbacks on runoff variability where both the

548   mean and snowmelt fraction are expected to increase as mountain topography grows. It is

549   conservative because biases in the water model data tend to dampen contrasts between rainfall

550   and snowmelt dominated hydrology, and thus our 1D bedrock river incision modeling uses

551   rulesets with weaker feedbacks than might be expected in reality (Forte & Rossi, 2023).

552   While analyzing the global water model data was motivated by prior studies that

553   identified an inverse relationship between mean runoff and daily runoff variability in the

554   contiguous U.S. (Molnar et al., 2006; Rossi et al., 2016), we felt it also important analyze the

555   global data more generically and explore whether hydro-climatic parameters can be linked to

556   topography itself. This latter objective is essential to building rules that relate stochastic runoff

557 parameters to mountain range growth and decay. To this end, we opted to use Random Forest

558 Regression to partition the relative influence of topographic, geographic, and hydro-climatic

559 predictors on a small subset of target variables.

560   5.3 Global relationships (Random Forest Regression)

561   Figure 6 summarizes the results of the random forest regression (RFR) analysis

562 performed on global, filtered WaterGAP3 data. While principally interested in understanding the

563 controls on mean runoff (Figure 6E-F), daily runoff variability (Figure 6G-H), and snowmelt

564 fraction (Figure 6I-J), we also consider influences on other hydro-climatological variables that

565 emerged as important determinants of these target variables, specifically mean annual

566 temperature (Figure 6A-B) and mean precipitation (Figure 6C-D). The results of the RFR are not

567 particularly surprising, but do shed some light on potential causal chains that links mean runoff,

568 snowmelt fraction, and daily runoff variability as a mountain range grows.

569   Mean annual temperature and mean precipitation are the two strongest predictors of both

570 mean runoff and snowmelt fraction, with temperature exerting a stronger influence on snowmelt

571 fraction and precipitation exerting a stronger influence on runoff. Mean runoff is the strongest

572 predictor of the shape of the daily runoff distribution, perhaps explaining why prior efforts have

573 focused on this relationship (e.g., Molnar et al., 2006; Rossi et al., 2016).

574   Importantly, topographic metrics were weak predictors of all three principal targets

575 (mean runoff, snowmelt fraction, daily runoff variability). This may be due to the fact that

576 topography is expected to exert its influence via precipitation and temperature. To assess this, we

577 also set mean precipitation and temperature as target variables in the RFR. The relative

578 predictive power of three topographic metrics and mean temperature on mean precipitation is

579   relatively uniform. In contrast, latitude is the strongest predictor of mean temperature with mean

580   elevation providing modest predictive power. At this scale of analysis, topography does not

581   appear to emerge as a strong predictor in the RFR modeling.

582   To further probe how topographic relationships might be obscured in this global analysis,

583   we binned the pixel-level data by its mean temperature and precipitation, which emerged above

584   as first-order controls on snowmelt fraction and mean runoff. We first removed outlier values

585   using the method described by Doane (1976) where bin boundaries are defined after clipping

586   variables to values below the 99.9th percentile. Membership in a given bin was determined by the

587   mean temperature and precipitation of the pixel in question. Within each temperature-

588   precipitation bin, we calculated Spearman's rank correlation coefficient between one of three

589   topographic metrics (mean elevation, maximum elevation, and mean local relief) and either mean

590   runoff or snowmelt fraction. A correlation coefficient is only calculated if there are at least 10

591   pixels within a given temperature-precipitation bin and if the significance of the correlation

592   coefficient exceeds the 95% confidence interval. We used Spearman's rank correlation

593   coefficient because it does not assume linear correlation.

594   Figure 7 summarizes the results of the correlation analysis of WaterGAP3 data after

595   binning by mean temperature and precipitation. The colors in plots show correlations between

596   topography and mean runoff (top row) and correlations between topography and snowmelt

597   fraction (bottom row). Green values indicate strong positive correlations, magenta values

598   indicate strong negative correlations, black values indicate weak to no correlation, and grey

599   values indicate that there was not enough observations in the dataset to evaluate correlation. The

600   patterns in correlation are somewhat difficult to interpret as clusters of strong positive

601   correlation are often adjacent to clusters of strong anti-correlation. Topographic predictors of

602   mean runoff show little sensible pattern (Figures 7A-C), with a hint of positive correlation

603   between local relief and mean runoff at low values of mean precipitation (Figures 7C).

604   Topographic predictors of snowmelt fraction are also complex with a band of positive correlation

605   for lower mean temperatures next to a band of anti-correlation at higher temperatures (Figures

606   7D-F). While we hesitate to interpret these subtle patterns, the snowmelt fraction results do

607   suggest that increasing topographic elevation and relief only leads to more snowmelt where

608   temperatures are conducive to it, though why this relation has a slope is not obvious.

609   As we discuss in more depth in the discussion below, the results from the global analysis

610   suggest that there is no single set of globally applicable 'rules' that relate topography to mean

611   runoff and snowmelt fraction. We suspect this is a consequence of the scale of the analysis (i.e.,

612   orographic effects are inherently regional) and the lack of accounting for the predominant

613   direction of weather systems with respect to topography (i.e., steep topography is not

614   distinguished as windward versus leeward). Based on this, we next explore a set of three regional

615   analyses that show more promise in constraining orographic controls on mean runoff and

616   snowmelt fraction.

617   5.4 Regional relationships of mean runoff and daily runoff variability

618   Given the challenge of identifying simple relationships between topography (i.e., mean

619   elevation, maximum elevation, and mean local relief) and either mean runoff or snowmelt

620   fraction (Figures 6-7), we now examine whether regional relationships between these variables

621   are being obscured by the global treatment. Of the six relationships shown in Figure 7, the

622   relationship between local relief and mean runoff and the relationship between maximum

623   elevation and snowmelt fraction seemed the most promising when evaluated spatially. Figure 8

624   summarizes the sign and strength of these relationships for all WaterGAP3 data that meet our

625   selection criteria. The zoom insets highlight three regions of interest – namely the mid-latitude

626   mountains of British Columbia, European Alps, and the Greater Caucasus. Each of these

627   mountain ranges receive a large fraction of their precipitation as snow, with some alpine

628   glaciation under modern climate. In these settings (and others), there is a relatively strong

629   correlation between local relief and mean runoff across the study area (Figure 8A-insets),

630   consistent with prior studies (Bookhagen & Burbank, 2006; Bookhagen & Strecker, 2008). The

631   relationship between maximum elevation and snowmelt fraction is more nuanced (Figure 8B-

632   insets). The sign of the correlation depends on whether positioned on the windward or leeward

633   side of prevailing weather systems, whereby windward sides show relatively strong positive

634   correlations. Nevertheless, the most complex of these three regional sites is the Greater

635   Caucasus, where relationships among maximum elevation, snowmelt fraction, and runoff

636   generation has been verified using a finer-scale analysis of gauge records and hydroclimatic data

637   (Forte et al., 2022). Taken as whole, this gives us confidence that these three locations are prime

638   candidates for building regional relationships among topography, snowmelt, and runoff statistics.

639   To develop these local relationships, we consider similar candidate relationships tested on the

640   global scale (Figure 7), specifically mean runoff or snowmelt fraction as a function of either

641   mean elevation, maximum elevation, or local relief (Figure S2).

642   **6 Discussion**

643   6.1 Mean runoff, runoff variability, and snowmelt

644   The global analysis of WaterGAP3 data helped solidify interpretations that mean runoff

645   and daily runoff variability are inversely correlated. This result was born out both in the Random

646   Forest Regression (Figure 6) and in the individual regressions after binning by snowmelt fraction

647   (Figures 4-5), thereby supporting findings from prior studies (Molnar et al., 2006; Rossi et al.,

648   2016). The functional form of the relationship between mean runoff and the shape of the daily

649   runoff distribution appears to bifurcate at snowmelt fractions around 0.35 (Figure 5). Below this

650   value, the relationship is highly nonlinear. Above this value, relationships vary but become much

651   more linear. The nonlinearity in rainfall-runoff regimes can be interpreted using ecohydrological

652   models where climatic parameters can exert different relative influences on mean and tail

653   behavior (Deal et al., 2018). The transition to snowmelt hydrology resulting in lower variability

654   flows (e.g., Pitlick, 1994) is expected due to the effects of both increased runoff ratios and the

655   slow release of water from storage. That this transition is abrupt emphasizes the importance of

656   the phase transition from rain to snow in event-scale runoff variability. The snowmelt fractions

657   where this occurs are relatively low suggesting that snowmelt should not be ignored in fluvial

658   erosion models. We also note here that stochastic-threshold models based on stream power were

659   originally developed for small watersheds (e.g., Lague et al., 2005; Tucker, 2004). Given our

660   focus on mountain range scales, it is important to also understand how the spatial footprint of

661   runoff events varies for different runoff generation mechanisms.

662   To assess the importance of spatial scale to runoff generation, Figure 9 compares the

663   exceedance frequency of the spatial footprints of precipitation and runoff events in the

664   WaterGAP3 data. The area of each 'event' is determined by finding spatially contiguous objects

665   in the daily data above a given intensity threshold (i.e., 5 - 35 mm/day). It should be noted that

666   unlike much of the analysis in previous sections, we do not filter by 'mountainous topography'

667   (i.e., use elevation or relief to filter the data), and are considering events across all land surfaces.

668   To convert the unprojected pixel-based objects into areas, we multiplied the number of pixels by

669   the size of a pixel in degrees squared. We then calculated the radius of the circle that equals that

670   area. The radius of the circle is converted from degrees to km in both latitude and longitude.

671   Because the conversion in longitude generally differs from the conversion in latitude, this

672   transformation produces an ellipse with area units of km^2. These are the x-coordinates used for

673   plotting exceedance frequencies (Figure 9A,C,E,G). Furthermore, for runoff data, we labeled

674   each event as snowmelt or rainfall runoff based on the 0.35 snowmelt fraction threshold. Because

675   smaller footprints include both rainfall and snowmelt dominated runoff, the right hand panels

676   (Figure 9B,D,F,H) shows the percent of daily runoff events that are classified as snowmelt for

677   log distributed bins of exceedance frequency. Three important insights emerge from this

678   analysis. First, and unsurprisingly, higher intensity thresholds produce smaller event areas.

679   Second, at around the 25 mm/day threshold, the largest area events in runoff and precipitation

680   (i.e., far right tails) are of similar magnitude. Higher thresholds produce runoff areas larger than

681   comparable frequency precipitation events. Third, the far right tail of the size distribution of

682   runoff is all snowmelt. Taken together, these results suggest that the relative contribution of

683   snowmelt runoff becomes increasingly important for larger watersheds and for increasing

684   intensities.

685   6.2 Importance of constraining regional relationships

686   While global relationships linking mean runoff and daily runoff variability via

687   topography were elusive, regional assessment was much more promising. Figure 10 summarizes

688   the kinds of regional rulesets that can be generated from an analysis like ours. At the regional

689   scale, relationships between local relief and mean runoff emerge, consistent with other studies

690   focused on explaining spatial patterns in rainfall (e.g., Bookhagen & Burbank, 2006; Bookhagen

691   & Strecker, 2008). This is thought to arise because high relief corresponds to increased forced

692   lifting of air masses. Local relief (not shown) and maximum elevation (shown) also correlate

693   with snowmelt fraction likely due to the role of high topography increasing the probability that

694   precipitation will fall in the form of snow. Regardless of mechanisms, our analysis shows the

695   value of producing regionally constrained links between mean runoff and snowmelt fraction via

696   topography. To generate Figure 10, the pixel-based correlation coefficients presented earlier

697   (Figure 8) are summarized into bins of either mean runoff or snowmelt fraction (y-axes). For

698   each bin, the mean and standard deviation of the correlated topographic metric is shown (local

699   relief for mean runoff and maximum elevation for snowmelt fraction). Marker sizes are scaled to

700   the number of observations within a bin. Power law fits for each relationship are shown as lines.

701   In detail, we tested whether better correlations existed between the hydroclimatic variables of

702   interest (mean runoff and snowmelt fraction) and either mean elevation, maximum elevation, and

703   mean local relief (Figure S2). The selected relationships shown in Figure 10, that we also use to

704   parameterize the models in Part 2, were chosen primarily based on either goodness of fit (i.e.,

705   which relationships had the lowest root mean squared error) or which ones would be more

706   practical to implement in the models developed in Part 2 when goodness of fit metrics were

707   similar. Each region is described by its own functional relationship, which we interpret as the

708   orographic effects on mean runoff and snowmelt fraction for each mountain range. We suspect

709   that some of the non-monotonic behavior of binned values, especially in snowmelt fraction, are a

710   consequence of mixing windward and leeward components of a regional orographic effect (e.g.,

711   Figure 8), as well as along-strike complexity in precipitation sourcing. Nevertheless,

712   summarizing the data in this way allows us to build empirically based rules for mean runoff and

713   snowmelt fraction specific to each region. Together with the observation that the relationship

714   between mean runoff and daily runoff variability abruptly shifts around snowmelt fractions of

715   0.35 allows us to drive a stochastic runoff model using regionally informed parameters from

716   WaterGAP3 in part 2 of this analysis (Forte & Rossi, 2023).

717   The relationships shown in Figure 10 help explain why the role of topography was so

718   hard to extract from the Random Forest Regression (RFR) that included these metrics (Figure 6).

719   First, regional relationships relating topography to runoff generation are quite noisy. While

720   casting runoff parameters as a simple function of topography was our goal, the relatively coarse

721   resolution of water model data, the lack of distinguishing between windward from leeward

722   slopes, and hydro-climatic diversity induced by regional climate will each confound simple

723   relationships between topography and runoff parameters. Second, while the power law functions

724   decently describe snowmelt fraction, the bin-averaged values suggest subtle, non-monotonic

725   relationships with maximum elevation. Third, and perhaps most importantly, the relationship for

726   each regional setting are distinctly different. Any global analysis would struggle to parse this

727   difference.

728   6.3 Implications on landscape evolution studies

729   Two-way coupled models between climate and tectonics require erosion laws for either

730   river incision, glacial erosion, or both. Those testing fluvial dynamics are typically built on the

731   stream power model (e.g., Beaumont et al., 1992; Stolar et al., 2006; Whipple & Meade, 2004;

732   Willett, 1999). Orographic effects in these models focus on the windward ascent and extraction

733   of precipitation. By setting up a contrast in the efficiency of erosion on the windward and

734   leeward sides of mountain ranges, mountain belts adjust their width and height in order to

735   achieve a steady state morphology. The widespread use of stream power in these climate-tectonic

736   models has subsequently motivated many studies to interrogate how orographically induced

737   spatial patterns in precipitation might alter the long-term evolution of river profiles and relief

738   (Anders et al., 2008; Han et al., 2014; Leonard & Whipple, 2021; Roe et al., 2002, 2003). At the

739   same time, stream power models are increasingly incorporating the role of stochastic streamflow

740   and erosion thresholds to interpret river profiles (DiBiase & Whipple, 2011; Lague, 2014; Lague

741   et al., 2005; Marder & Gallen, 2023; Scherler et al., 2017; Snyder et al., 2003; Tucker, 2004;

742   Tucker & Bras, 2000). The aim in this study was integrate these two productive research threads

743   and explore whether mean runoff, daily runoff variability, and snowmelt fraction can be linked to

744   each other via topographic elevation and relief. As such, we focused our regional analyses on

745   mid-latitude mountain ranges at or near the cusp of glaciation, and where snowmelt contributions

746   to streamflow are significant. While this was our focus, it is worth noting that orographic

747   gradients in stochastic rainfall itself are often poorly constrained. For example, in tropical

748   settings, there can be complex interactions among rainfall type (e.g., convective, monsoonal) that

749   can lead to lower elevation peaks in rainfall maxima (Anders & Nesbitt, 2015) than conventional

750   orographic rules assume, a topic in need of more attention.

751   Figure 11 is a conceptual diagram illustrating how stochastic runoff parameters might co-

752   evolve with mountain topography in settings where mountain range relief is sufficient to trigger

753   the transition from rainfall-dominated to snowmelt-influence runoff, but where river incision is

754   still setting the relief structure of the landscape (e.g., Whipple et al., 1999). The color coded dots

755   on the schematic mountains in Figure 11A are intended to correspond to the dots on the

756   hypothetical plots relating topography to runoff and snowmelt (Figure 11B) and those relating

757   mean runoff to daily runoff variability (Figure 11C). On the windward side of mountain ranges

758   we expect that the growth of topography will increase mean runoff (Figure 11B solid line) in line

759   with conventional treatments of orographic precipitation (Roe, 2005). This leads to concurrent

760   increases in the frequency of snowfall and thus the snowmelt contribution to runoff (Figure 11B

761   dashed line). While snowmelt fraction has an upper bound of one, in practice, the upper bound

762   we are envisioning in Figure 11B will be less than one because rain continues to fall at lower

763   elevations and because the temperatures required to enhance very high snowmelt fractions would

764   also entail a transition to glaciation. The key behavior in this conceptual framework is that

765   accounting for snowmelt dynamics leads to a markedly different relationship between mean

766   runoff and the shape parameter of the daily runoff distribution (Figure 11C). Our global analysis

767   of WaterGAP3 data suggests that this transition might be abrupt. We identified a snowmelt

768   fraction of ~0.35 corresponds to this transition, with the important caveat that this is based on a

769   water model dataset that tends to produce underestimates of the shape parameter (Figure 3B).

770   Furthermore, while the bulk of the data supports the notion that this transition is relatively

771   abrupt, there are a number of exceptions to this pattern in both the water model and observational

772   data (Figures 1B; 4; 5A). These exceptions may be due uncertainty in the proposed snowmelt

773   transition or evidence for the numerous other hydrological considerations that can reduce daily

774   variability in rainfall-dominated regimes (e.g., seasonality, groundwater, drainage basin size).

775   Regardless, the global analysis reveals that the strength and form of these relationships need to

776   be assessed independently for any given mountain range (Figure 10). However, by simplifying

777   the hydrology into just two parameters, these kinds of relationships are well-suited to driving

778   long term models of river incision (e.g., Lague et al., 2005; Tucker, 2004) in ways that can be

779   linked to mean climate (DiBiase & Whipple, 2011) and ecohydrology (Deal et al., 2018).

780   While we think there is observational evidence for these dynamics in actual landscapes

781   (Forte et al., 2022), we highlight a few important caveats to generalizing from our large-scale

782   analysis of the WaterGAP3 water model data. First, this conceptual model is better suited to

783   explaining the windward side of mountain ranges where precipitation, and thus runoff, is

784 enhanced by topography. To build better rulesets, higher resolution runoff datasets that honor

785 physiographic transitions and water divides are likely needed. Second, this conceptual model

786 requires that mean runoff and rare runoff events are linked via some common mechanism. This

787 need not be the case. For example, recent work in the Colorado Front Range showed how mean

788 runoff was largely driven by snowmelt throughout the landscape while daily runoff variability

789 was driven by rainfall runoff at lower elevations in response to thinning soils (Rossi et al., 2020).

790 Such mechanistic controls on mean runoff and daily runoff variability are at play in all

791 landscapes and may partially explain the wide variance of runoff parameters observed in our

792 regional rulesets (Figure 10). Third, statistical analyses all assumed independence of daily runoff

793 events which is decidedly not true as runoff events, especially large ones, can extend over

794 multiple days (synoptic-scale storms) to seasons (snowmelt, monsoons). Despite these caveats,

795 this analysis produced empirically-based runoff parameters that vary in space and time. As such,

796 this provides the minimal constraints needed to integrate orographic effects with stochastic

797 runoff generation for river profile modeling (Forte & Rossi, 2023).

798 **7. Conclusions**

799   The results of our global analysis of WaterGAP3 data largely confirm, and significantly

800 expand upon, past results indicating a negative correlation between mean runoff and daily runoff

801 variability. The form of the relationship between variability and mean runoff is linked to the

802 fraction of runoff from snowmelt. For snowmelt fractions <0.35, mean runoff and variability are

803 related via a power law. At higher snowmelt fractions, the two are linearly related. We also find

804 that snowmelt produces runoff events with a much larger areal extent than rainfall runoff.

805   Exploration of the extent to which mean runoff, runoff variability, and snowmelt fraction

806 are related to topography produces ambiguous results at the global scale. Unsupervised machine

807 learning methods highlight that simple topographic variables such as mean elevation, maximum

808 elevation, and local relief do not have strong predictive power for our target hydroclimatological

809 parameters of mean runoff, snowmelt fraction, and daily runoff variability. Attempts to identify

810 cross-correlations that may be masking the role of topography were more suggestive, but still

811 difficult to interpret. Results from the global analysis emphasize that exploring relationships

812 between topography and hydroclimatology requires a regional approach. For three mid-latitude

813 mountain ranges - the European Alps, Greater Caucasus, and southern British Columbia – we

814 find robust positive relationships between mean runoff and mean local relief and snowmelt

815 fraction and maximum elevation.

816 The links between topography, mean runoff, daily runoff variability, and snowmelt

817 fraction highlight that multiple aspects of hydroclimate of mountain ranges should be expected to

818 evolve as topography grows. Past work on this topic has primarily focused on the influence of

819 growing topography on the development of orographic patterns in rainfall. When coupled to

820 tectonic models and simple hydrologic models equating patterns in mean rainfall to mean runoff,

821 orographic effects have been shown to drive a variety of feedbacks between surface processes

822 and tectonics. Our results show how to move beyond mean precipitation or mean runoff when

823 considering the coupled evolution of topography, tectonics, and climate. Both snowmelt fraction

824 and mean runoff are expected to increase with growing topography and reduce daily runoff

825 variability, emphasizing the need to explicitly consider snowmelt dynamics in coupled tectonic –

826 landscape evolution models.

835   Analysis codes necessary to reproduce this work are available in Forte (2024). Larger

836 outputs of the processing steps are available in Forte & Rossi (2024). Portions of these analysis

837 codes rely on publicly available datasets that we do not have permission to redistribute, but when

838 used, we provide comments in the code referencing where these datasets can be downloaded.

839

840
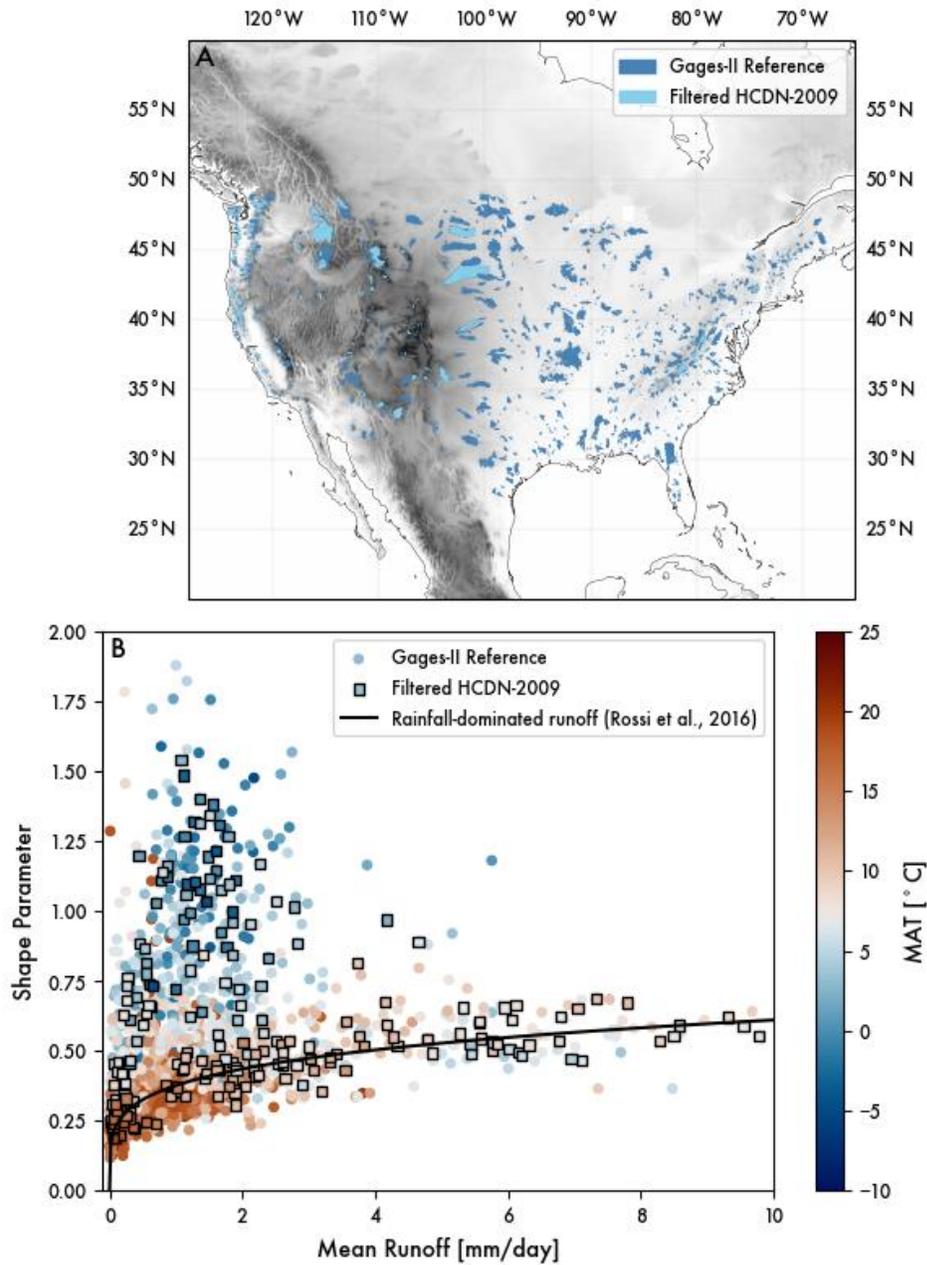

Figure 1. Observational stream gauge data used in this study includes (A) gauged sites in the

contiguous United States that are minimally impacted by human management, which are then

used to characterize (B) the relationship between mean runoff and the shape parameters

describing daily runoff distributions for each stream gauge. In A, a subset of the reference

stations in the GAGES-II network were used for the water model validation presented below

846   (i.e., filtered HCDN-2009). In B, two broad trends between mean runoff and daily runoff

847   variability organize around mean annual temperature, which prior authors have interpreted as

848   reflecting the transition from snowmelt-dominated to rainfall-dominated systems (Rossi et al.,

849   2016).
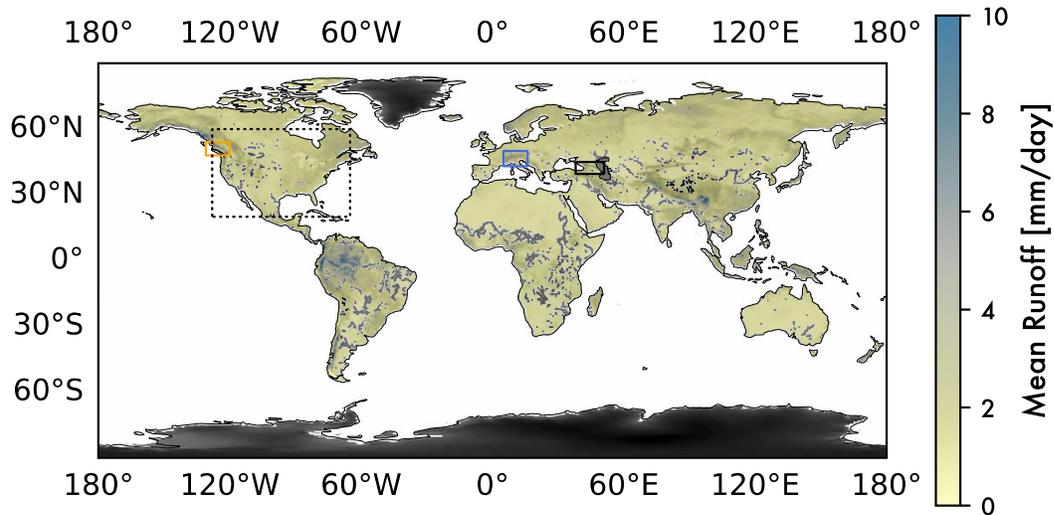

850

851   **Figure 2.** Global mean runoff from the WaterGAP3 water model (1980-1999). The dotted black

852   box corresponds to the area shown in Figure 1A and bounds the geographic extent of the

853   validation data used. The three smaller colored boxes show the geographic extent of the three

854   mid-latitude, regional case studies introduced in section 4.4.

855

856
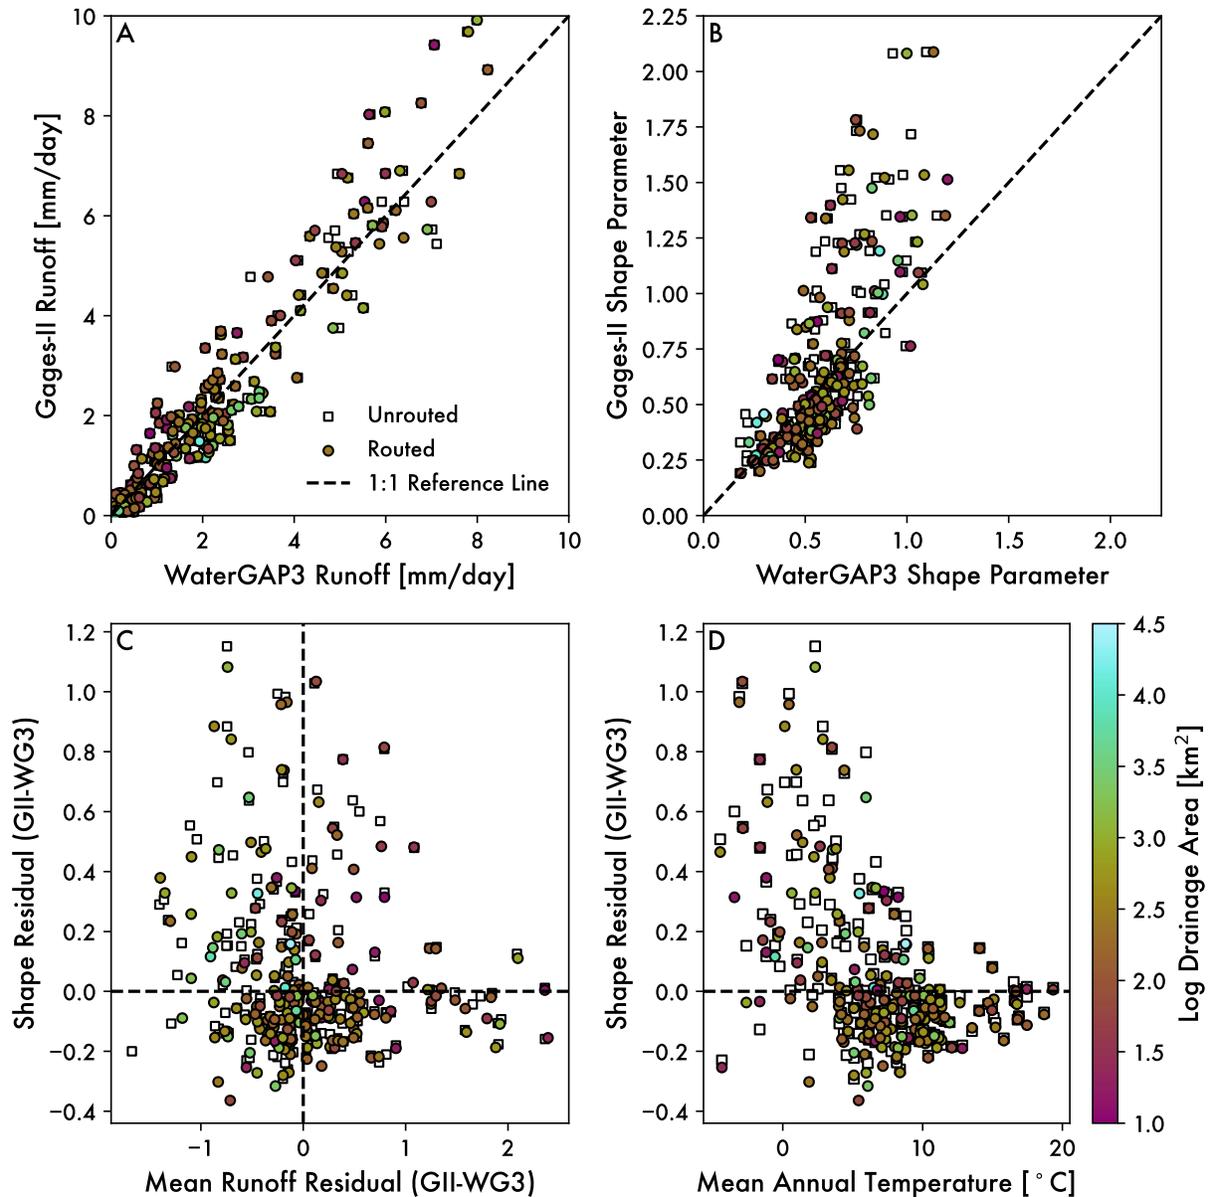

Figure 3. Comparison of WaterGAP3 runoff parameters against selected HCDN-2009 stream

gage data, colored by the log of the drainage area of individual gaged basins: (A) Mean runoff

values, (B) Shape parameters of daily distributions, (C) Mean and shape residuals with respect to

1:1 line, and (D) Shape residuals against mean annual temperatures for each watershed. Open

squares are arithmetic means of WaterGAP3 values within watershed boundaries. Closed and

colored circles route daily WaterGAP3 data to generate a time series that is then used to calculate

863   fit parameters. Dashed lines in the upper panels indicate the 1:1 relationship between the water

864   model and gaged data whereas dashed lines in the lower panels reflect a 0 residual value.
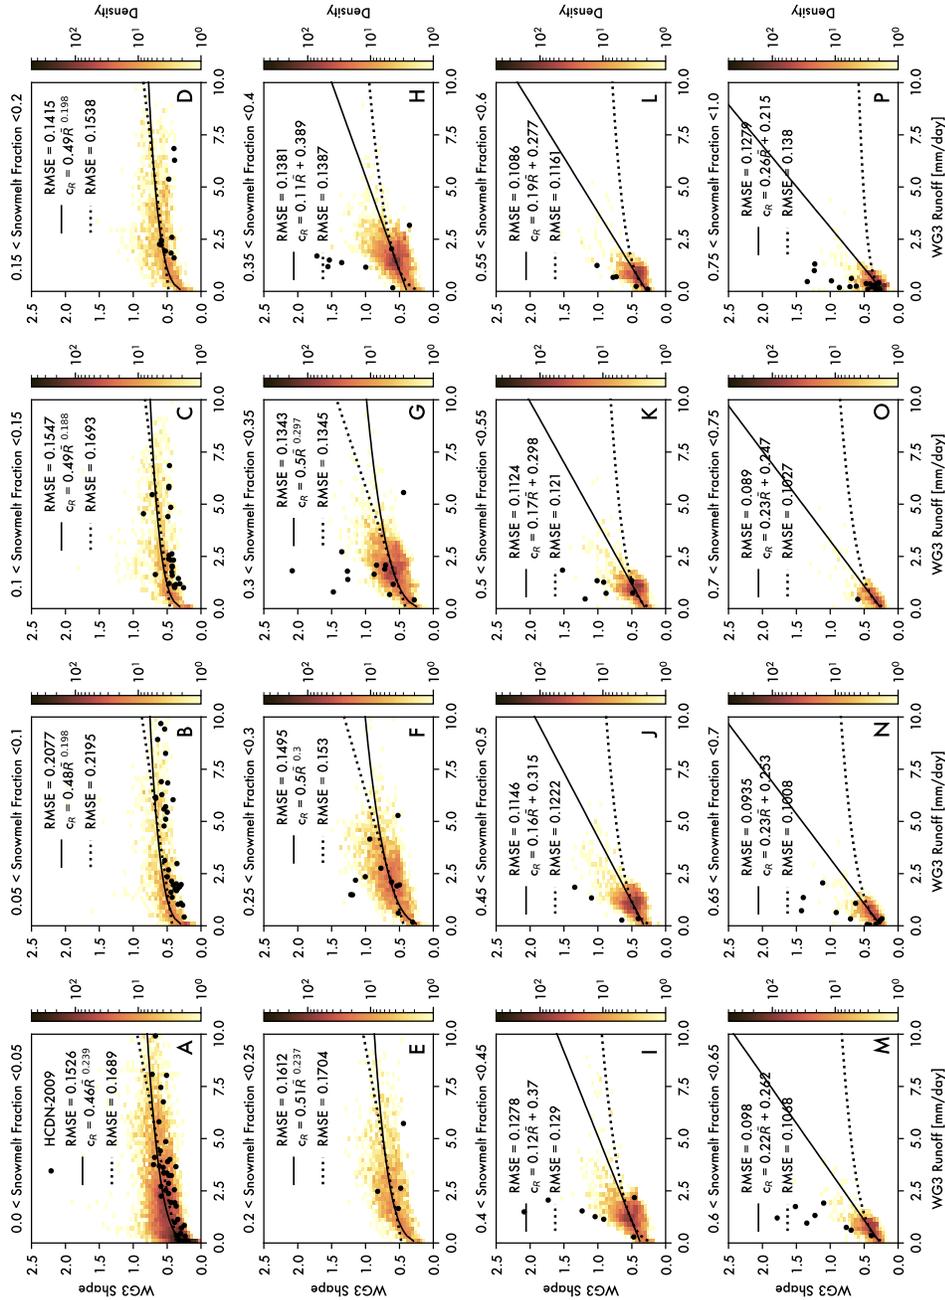

865

866   **Figure 4.** Density plots show the relationship between the shape parameter and mean runoff for

867   the filtered WaterGAP3 data: (A-O) Plots binned by snowmelt fraction in increments of 0.05 up

868   to 0.75 snowmelt. (P) The last panel is for the remaining data that has >0.75 snowmelt. In all

869   panels, both a power law and linear fit are shown. The better fit is shown using a solid line and is

870   based on having a lower RMSE. Results are the same if using the reduced chi squared statistic.

871   Black dots are HCDN-2009 watersheds filtered in the same way. For HCDN-2009 data,

872   snowmelt fraction was taken from WaterGAP3 data.

873
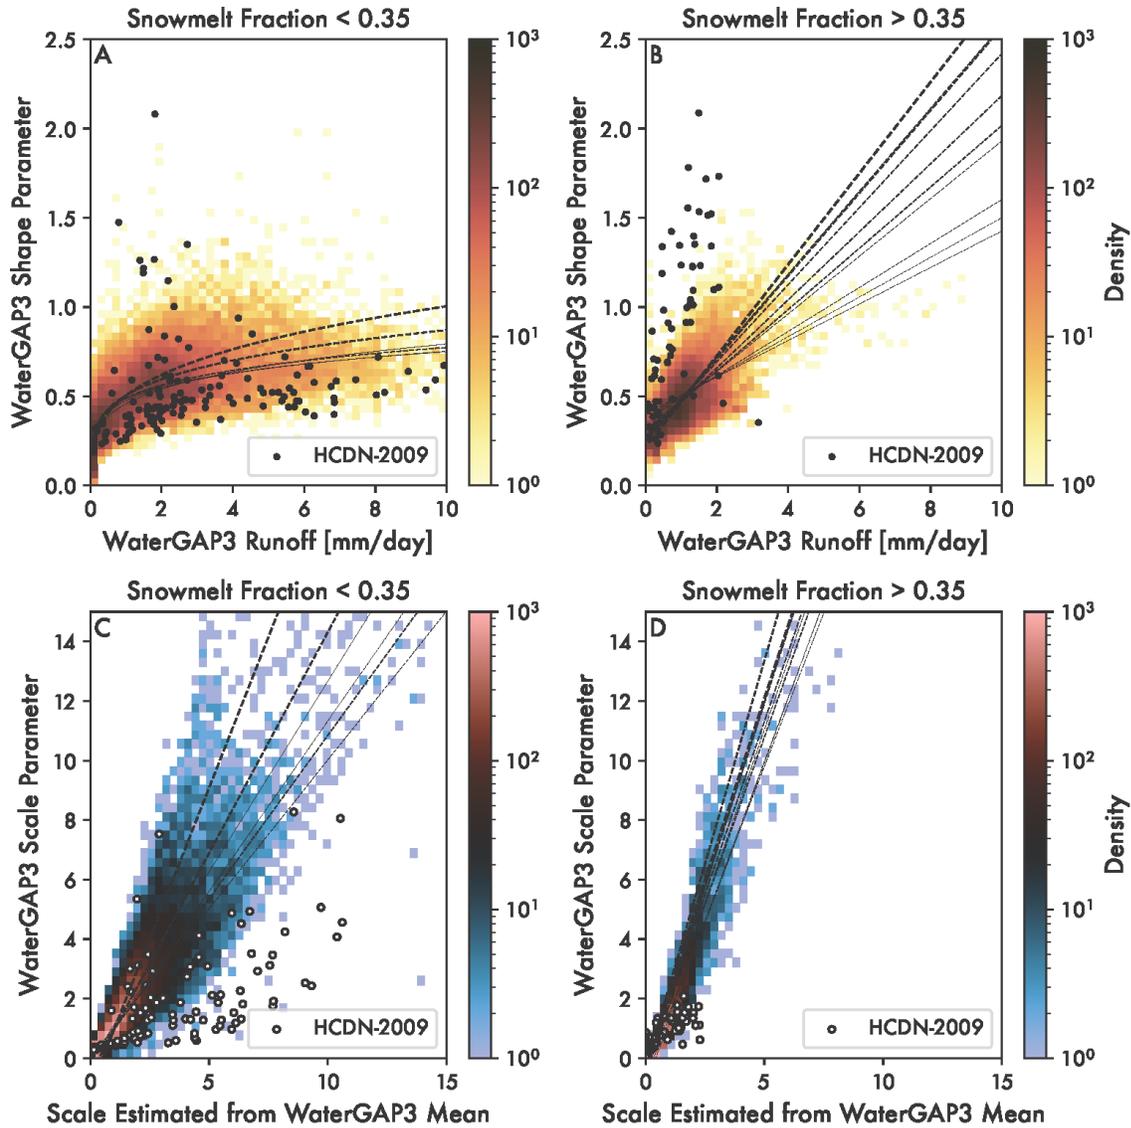

Figure 5. Density plots showing relationships among the scale and shape parameters of

875   parametric fits with the mean runoff observed for the filtered WaterGAP3 data. (A) Relationship

876   between mean runoff and shape of the right tail for pixels where snowmelt fraction is <0.35. (B)

877   Relationship between mean runoff and shape of the right tail for pixels where snowmelt fraction

878   is >0.35. Because parametric fits include a threshold, the mean of the distribution cannot be

879   directly inferred from scale parameters. (C) Relationship between the scale parameters fit to the

880   data versus those implied from the empirical mean for pixels where snowmelt fraction is <0.35.

881   (D) Relationship between the scale parameters fit to the data versus those implied from the

882   empirical mean for pixels where snowmelt fraction is >0.35.Black dots are HCDN-2009

883   watersheds filtered in the same way. The strongest regressions from Figure 4 (A-B) and Figure

884   S1 (C-D) subpanels are shown for reference.

885

886
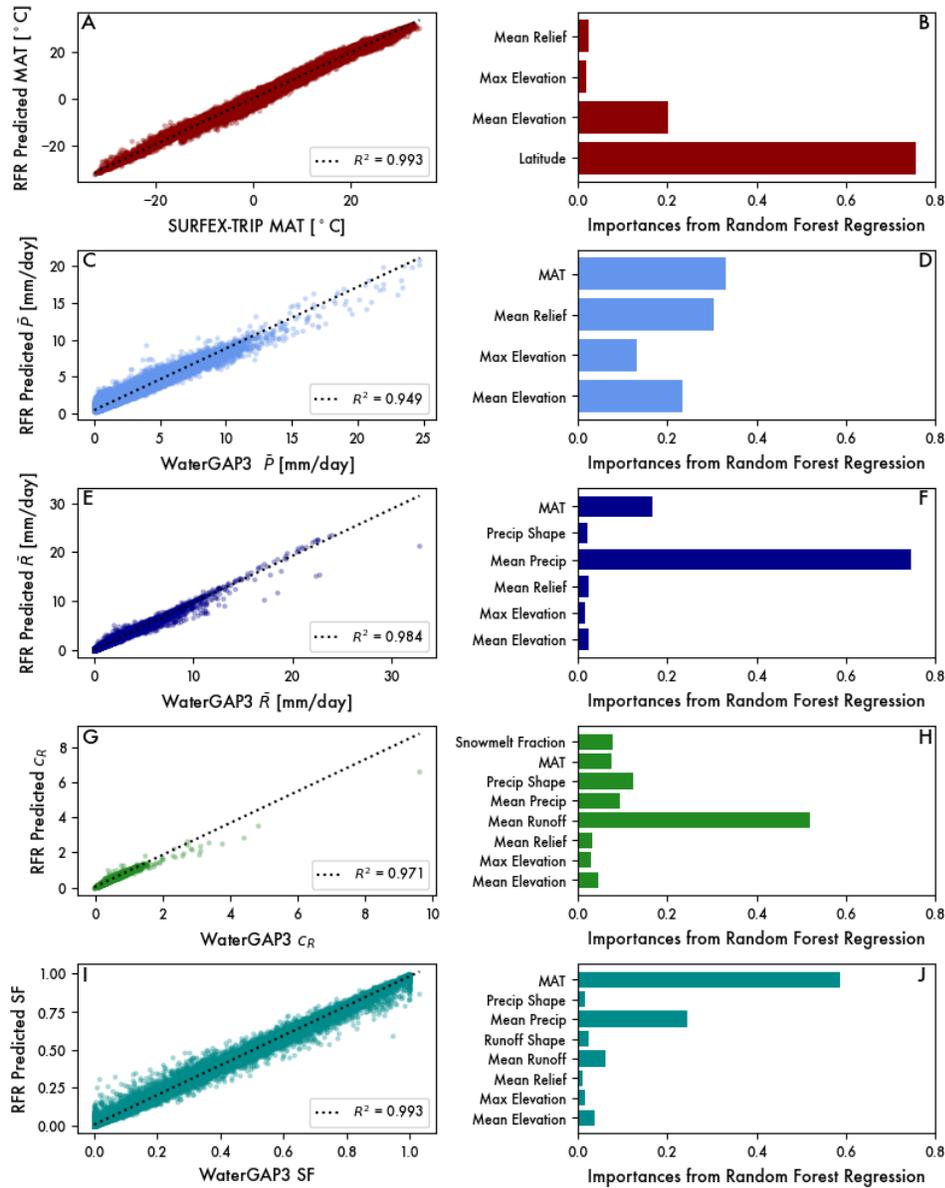

Figure 6. Results from the random forest regression for predicting: (A-B) Mean Temperature,

(C-D) Mean Precipitation, (E-F) Mean Runoff, (G-H) Runoff Variability, and (I-J) Snowmelt

889   Fraction. For each target variable, the left plot compares observed versus predicted data (linear

890   fit with R^2 shown for reference), and the right plot shows the relative importance of predictors.

893
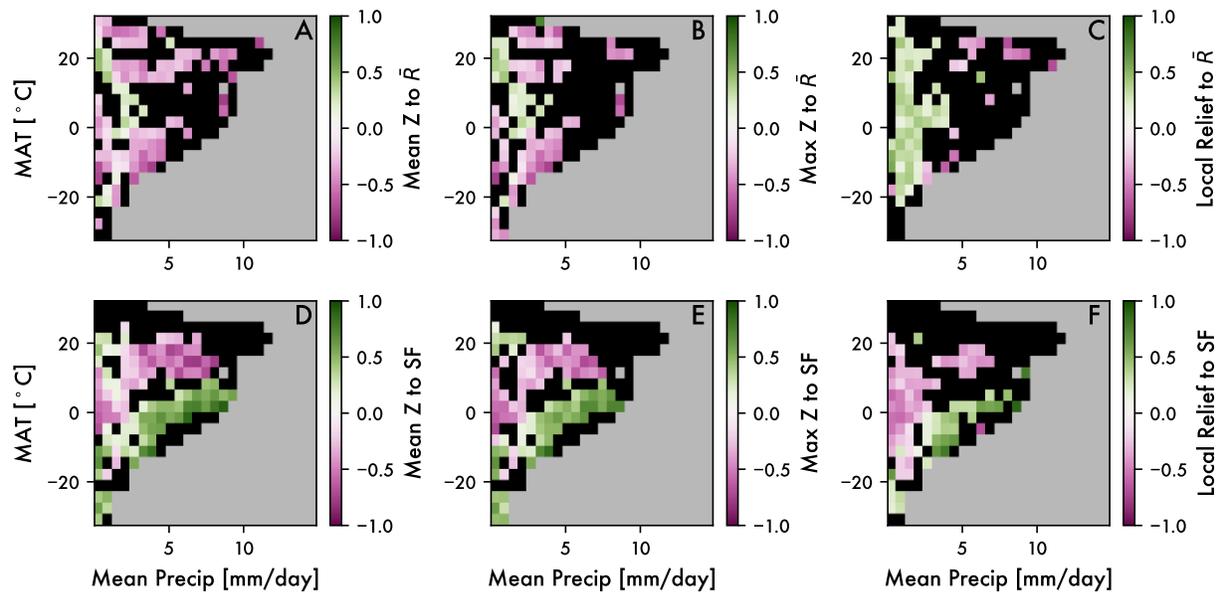

Figure 7. Spearman's rank correlation coefficients within temperature-precipitation bins. (A-C)

Coefficients relating topography and mean runoff. (D-F) Coefficients relating topography to

snowmelt fraction. The topographic variables considered were mean elevation (A, D), maximum

elevation (B, E), and local relief (C, F). For all plots, the gray area indicates regions of parameter

space with less than 10 observations. Black regions indicate there were greater than 10

observations, but that the correlation did not exceed the 95% confidence interval. Note that these

plots obscure the number of observations in each precipitation – temperature bin. As such, see

Figure 8 to assess the distribution of correlations coefficient within their spatial context.

902

903
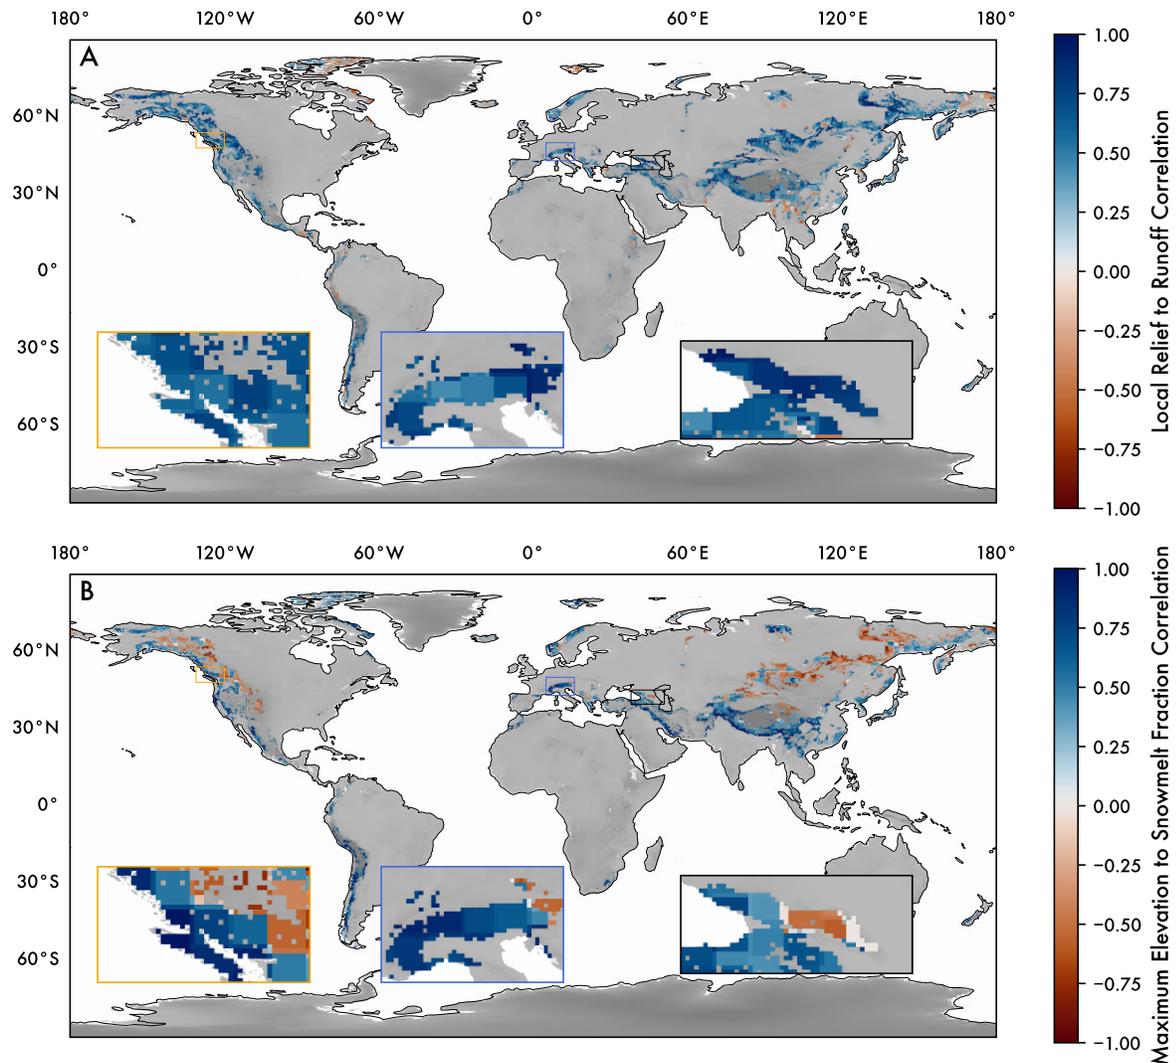

Figure 8. Relationships among topography, mean runoff, and snowmelt fraction in map view.

(A) Mean spearman rank correlation coefficient within a 2° moving window for mean runoff and

local relief. (B) Mean spearman rank correlation coefficient within a 2° moving window for

maximum elevation and snowmelt fraction. After filtering the WaterGAP3 data for mountain

settings (see text for details), only a small area remains. Insets highlight results for the three

regional cases considered.

910

911
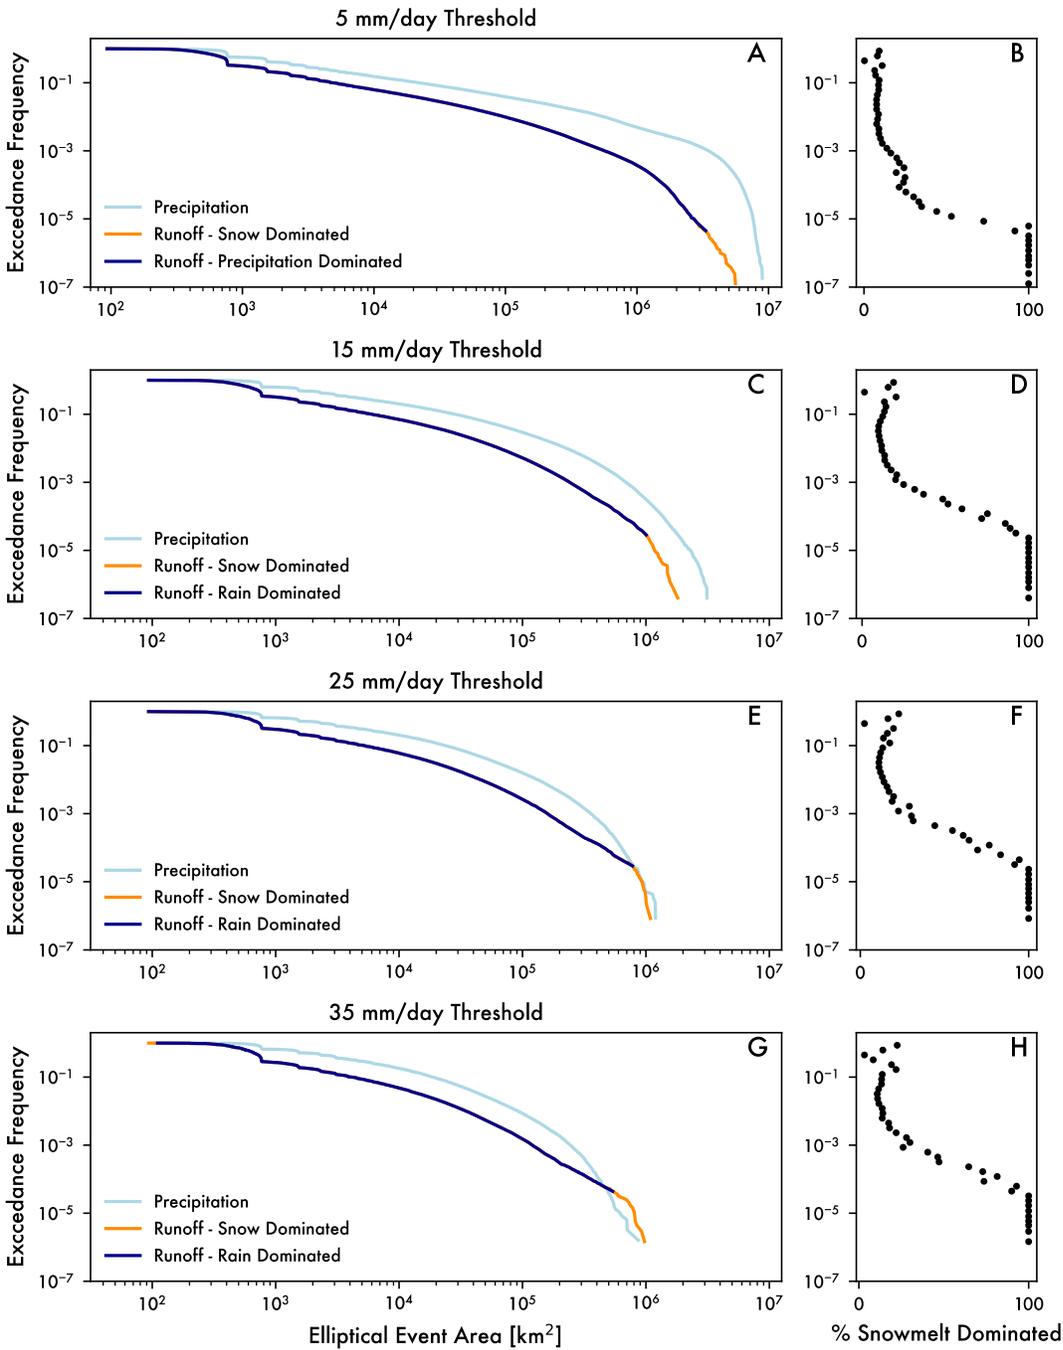

Figure 9. Exceedance probability distributions of daily event sizes of different magnitudes: (A-

B) 5 mm/day, (C-D) 15 mm/day, (E-F) 25 mm/day, and (G-H) 35 mm/day. The left panels show

probability plots for both precipitation and runoff, whereby the latter is color-coded by runoff

generation source. After classifying runoff events in this way, the right panels show what

916   fraction of events are snowmelt dominated within exceedance probability bins. Note that

917   regardless of intensity threshold the largest area runoff events are snowmelt dominated. At

918   higher intensity thresholds, these event sizes can exceed the largest area precipitation events.

919
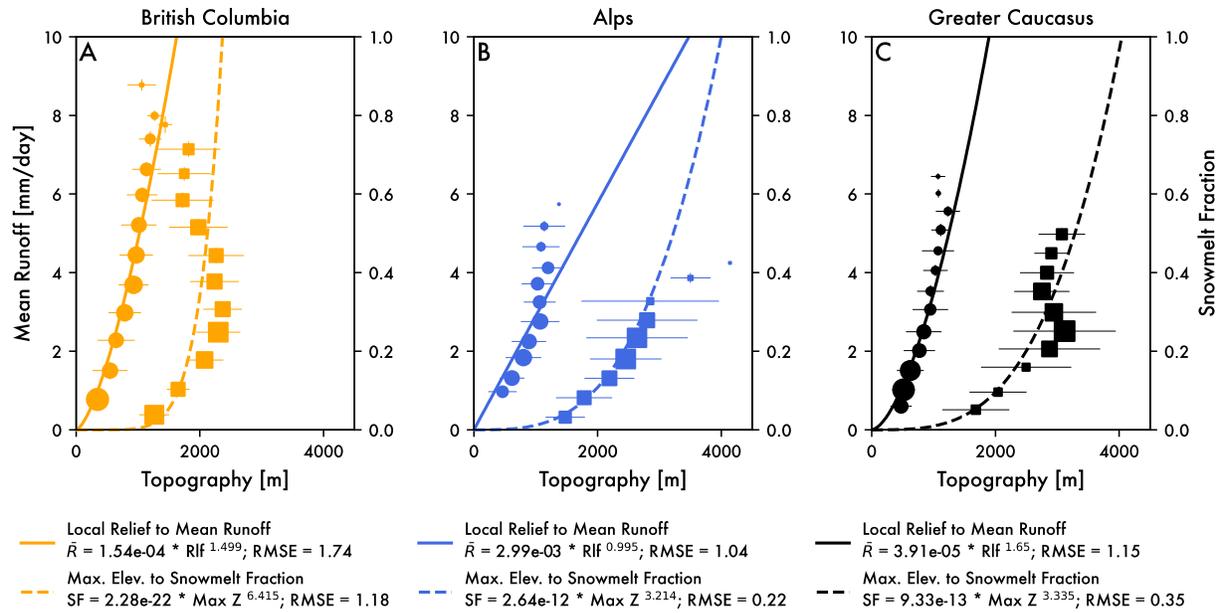

920

921   **Figure 10.** Relationships among topography, mean runoff, and snowmelt fraction for the three

922   regional cases (see Figure 8 for locations): (A) British Columbia, (B) European Alps, and (C)

923   Greater Caucasus. In all three plots, circles are binned mean runoff to local relief, and squares

924   are binned snowmelt fraction to maximum elevation. Symbols are scaled to number of

925   observations in the bin and whiskers show one standard deviation. Power law fits for binned data

926   relate local relief and mean runoff (solid line) and maximum elevation and snowmelt fraction

927   (dashed line). In all three panels, the "Topography" x-axis plots both local relief (solid line) and

928   maximum elevation (dashed line). These fits serve as the basis for orographic rules used in our

929   complementary model study (Forte & Rossi, 2023).

930
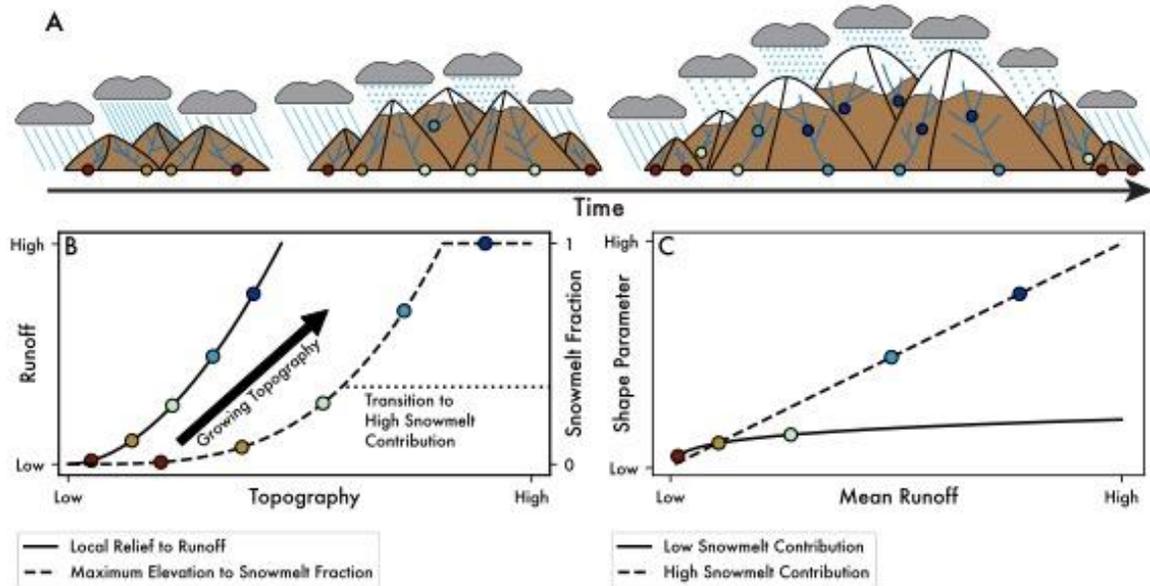

931

932   **Figure 11.** Conceptual model for how orographic controls on runoff variability can be

933   represented in a landscape evolution model. (A) Cartoon showing how precipitation and runoff

934   generation mechanisms might change as a mountain range grows. (B) Example rules for how

935   topography is translated into more runoff and a larger snowmelt fraction as topography grows.

936   (C) Relationship between mean runoff and daily runoff variability in response to those rules. In

937   B, the example ruleset shows that as mountain topography grows, increasing relief leads to more

938   runoff generation on the windward side of a mountain range and increasing elevations lead to a

939   higher fraction of snowmelt. In C, these topography-runoff relationships translate into a much

940   different relationship between mean runoff and daily runoff variability that encodes the transition

941   from rainfall- to snowmelt-dominated runoff events.
