Key Points:

- Implemented a trait-based model of dynamic phytoplankton elemental stoichiometry within global biogeochemical simulations.
- Dynamic stoichiometry decreased phytoplankton P-limitation in the tropics and subtropics and increased N-fixation and export.
- Frugal P-utilization in low P environments and increased P-rich ribosomes at high growth rates leave distinct biogeochemical fingerprints.

Abstract

Phytoplankton stoichiometry modulates the interaction between carbon, nitrogen and phosphorus cycles, yet most biogeochemical models represent phytoplankton C:N:P as constants. This simplification has been linked to Earth System Model (ESM) biases and potential misrepresentation of biogeochemical responses to climate change. Here we integrate key elements of the Adaptive Trait Optimization Model (ATOM) for phytoplankton stoichiometry with the Carbon, Ocean Biogeochemistry and Lower Trophics (COBALT) ocean biogeochemical model. Within a series of global ocean-ice-ecosystem retrospective simulations, ATOM-COBALT reproduced observations of particulate organic matter N:P, and compared to static N:P, exhibited reduced phytoplankton P-limitation, enhanced N-fixation, and increased low-latitude export, leading to improved consistency with observations. Two mechanisms together drove these patterns: the growth hypothesis and frugal P-utilization during scarcity. The addition of translation compensation-differential temperature dependencies of photosynthetic relative to biosynthetic processes led to relatively modest strengthening of N:P variations and biogeochemical responses relative to growth-plus-frugality. Comparison of the multi-mechanism model herein against frugality-only models suggest that both can capture observed N:P patterns and produce qualitatively similar biogeochemical effects. There are, however, quantitative response differences and different responses across N:P mechanisms are expected under climate change- with the growth rate mechanism adding a distinct biogeochemical footprint in highly-productive low-latitude regions. These results suggest that variable phytoplankton N:P makes some biogeochemical processes resilient to environmental changes, and support using dynamic N:P formulations with the ocean biogeochemical component of next generation of ESMs.

Plain Language Summary

Marine phytoplankton are single-celled photosynthetic organisms that live near the ocean's surface, where they absorb carbon dioxide and other nutrients. This exerts a large influence on ocean chemistry and, through the ocean's capacity to absorb carbon dioxide from the atmosphere, the Earth's climate. We explored how phytoplankton vary their requirements (also known as stoichiometry) for two essential nutrients, nitrogen and phosphorus, based on environmental conditions, and how that variation affects the export of carbon from the surface ocean to depth. We found that flexibility in phytoplankton

stoichiometry makes them use phosphorus more efficiently, driving an increase in carbon export. It also stimulates nitrogen fixation, causing an increase in nitrogen available to phytoplankton. As a result, our simulations predicted significantly less phosphorus limitation and more export from low-latitude parts of the ocean, increasing agreement with observations. Flexible phytoplankton stoichiometry changes how marine ecosystems respond to the environment, and understanding how stoichiometry varies is key to predicting how the ocean will respond to future changes.

1 Introduction

Marine phytoplankton facilitate carbon (C) sequestration from the atmosphere to the deep ocean, forming a crucial part of the biological carbon pump and regulating ocean chemistry and global climate. Primary productivity and C-export tightly couple to the biogeochemical cycles of nitrogen (N), phosphorus (P), and iron (Fe), because the availability of these resources can limit the growth of phytoplankton. The elemental stoichiometry of phytoplankton, defined as the ratio of C:N:P in the organic matter of their cells, helps determine how strongly the C, N, and P cycles interact.

A prominent and useful paradigm in biological oceanography holds that C:N:P ratios can be approximated as constants that reflect global means, known as the *Redfield Ratios* (Redfield, 1958), (typically 106:16:1). However, recent observations reveal systematic variations of the C:N:P of organic matter, exceeding Redfield in subtropical gyres and the tropics and falling below Redfield in high-latitudes (Martiny, Pham, et al., 2013). This has consequences for the C-cycle and the response of the oceans to global change, impacting relationships between nutrient availability and export, as well as feedbacks that depend on physiological mechanisms that regulate C:N:P (Deutsch & Weber, 2012; Galbraith & Martiny, 2015; Moreno et al., 2018).

Despite recent observations of variations in phytoplankton elemental stoichiometry, Earth System Models (ESMs) rarely capture dynamic C:N:P, with most opting to use Redfield ratios or fixed stoichiometry for different phytoplankton size classes (Danabasoglu et al., 2020; Séférian et al., 2020). While these models capture many large-scale observed biogeochemical patterns, static stoichiometry has been linked to a number of significant biases. For example, the relatively comprehensive Carbon Ocean Biogeochemistry and Lower Trophic (COBALT) ocean biogeochemical model used in Earth System simula-

25 tions contributed by the Geophysical Fluid Dynamics Laboratory to the 6th Coupled
26 Model Intercomparison Project (CMIP6) (J. Dunne et al., 2020; Stock et al., 2020) im-
27 posed static characteristic C:N:P ratios for each of three phytoplankton types. This led
28 to muted N:P variations and was linked to an over-expression of P-limitation and a sup-
29 pression of nitrogen fixation (Stock et al., 2020). Similar issues arose in other ESMs us-
30 ing fixed or highly simplified C:N:P ratios (Martiny et al., 2019), leading to a growing
31 number of efforts to address this limitation in ESMs (Kwiatkowski et al., 2018; Tanioka
32 & Matsumoto, 2017; Long et al., 2021).

33 Several mechanisms have been proposed to explain the observed C:N:P patterns
34 (Moreno & Martiny, 2018): the *growth rate hypothesis* holds that rapidly growing cells
35 require more P-rich ribosomes (Elser et al., 2000), leading to lower C:N:P in eutrophic
36 ecosystems and higher in oligotrophic ones. The *translation compensation hypothesis* sug-
37 gests that the increased efficiency of protein synthesis in warmer waters relative to pho-
38 tosynthesis (Devault, 1980) leads to fewer ribosomes and higher C:N:P in warm waters.
39 Lastly, the *frugality hypothesis* postulates that cells decrease their quota of scarce resources,
40 causing C:N:P to anti-correlate with phosphate (Galbraith & Martiny, 2015) due to higher
41 plasticity of P-quotas compared with C and N. Covariation between observed temper-
42 ature, nutrients, and food web structure had previously hindered attempts to disentangle
43 these mechanisms, discouraging the use of dynamic C:N:P in ESMs. Observational
44 advances, however, have facilitated recent papers (Moreno et al., 2018; Kwiatkowski et
45 al., 2018; Matsumoto et al., 2020; Pahlow et al., 2020; Bopp et al., 2022; Kwon et al.,
46 2022; Chien et al., 2023), which study the centrality of these mechanisms for the cur-
47 rent and future controls on carbon export and nitrogen fixation, through both direct changes
48 in nutrient utilization and novel interactions driven by differences in C:N:P between ocean
49 regions and lateral nutrient transport.

50 Future ocean warming may cause an expansion of oligotrophic gyres, with projected
51 negative impacts on primary productivity, carbon export, and biomass available for higher
52 trophic levels (Bopp et al., 2013; Moore et al., 2018). However, high phytoplankton di-
53 versity could enable them to rapidly adapt to warmer, lower nutrient conditions, pos-
54 sibly mitigating these expected changes (G. I. Hagstrom & Levin, 2017; Martiny, Hagstrom,
55 et al., 2022). Dynamic phytoplankton N:P provides one mechanism whereby plankton
56 can buffer against these environmental shifts, however in order to study the potential

57 for this to occur, biogeochemical models need to better capture the adaptive capacity
58 of phytoplankton.

59 To answer these questions, we integrated elements of ATOM (Adaptive Trait Op-
60 timization Model), a *trait-based model* (Litchman & Klausmeier, 2008) of phytoplank-
61 ton C:N:P (C. A. Garcia et al., 2020; Moreno et al., 2018), with the Carbon, Ocean, Bio-
62 geochemistry, and Lower Trophics (COBALT) marine ecosystem model (Stock et al., 2014,
63 2020). ATOM predicts phytoplankton biomass investments in photosynthesis, biosyn-
64 thesis, structure, and storage, using traits to efficiently represent substantial phytoplank-
65 ton diversity and to simulate their adaptation to changing conditions. Here, we recast
66 ATOM to fit the fixed size classes present in COBALT. We ask the following questions:
67 (1) how does a trait-based (or optimality based) model predict both optimal and real-
68 ized phytoplankton stoichiometric ratios in the global oceans, (2) how do these stochio-
69 metric ratios impact marine ecosystem function and biogeochemical cycling, (3) what
70 role do each of the following three mechanisms (growth rate, translation compensation,
71 and frugality) play in determining biogeochemical patterns?

72 2 Methods

73 2.1 COBALT

74 The base configuration of COBALT simulates global scale cycles of carbon, nitro-
75 gen, phosphorus, iron, silica, calcite, aragonite, and lithogenic materials using 33 trac-
76 ers (Stock et al., 2014, 2020). The most pertinent aspect for integration with ATOM is
77 the formulation for phytoplankton growth and nutrient uptake, which we describe here.
78 COBALT represents three size classes of phytoplankton, a small phytoplankton param-
79 eterized to emulate cyanobacteria like *Synechococcus* and *Prochlorococcus*, a large phy-
80 toplankton parameterized to emulate diatoms, and a diazotroph parameterized to em-
81 ulate *Trichodesmium* (see Fig. 1, upper left). We will denote the differences between phy-
82 toplankton types by the subscripts (*sp*, *lp*, *diazo*) for small, large, and diazotroph, in ex-
83 pressions where the types have different functional responses. Following Geider (Geider
84 et al., 1997), COBALT modeled the growth rate of a phytoplankton population using
85 the following expression:

$$\mu = \frac{P_{cm}}{1 + \zeta} \left(1 - \exp \left(\frac{-\alpha_{PI} \theta \text{Irr}}{P_{cm}} \right) \right) \quad (1)$$

86 where P_{cm} is the maximum photosynthesis rate allowed by a given temperature and nu-
 87 trient concentration, ζ is the cost of biosynthesis, α_{PI} is the Chl-specific initial slope of
 88 the photosynthesis-irradiance curve, θ is the Chl:carbon ratio, and Irr is the instanta-
 89 neous irradiance.

The Chl:carbon ratio depends on the past history of irradiance Irr_{mem} :

$$\theta = \frac{(\theta_{\max} - \theta_{\min})}{\left(1 + \frac{\theta_{\max} \alpha_{PI} \text{Irr}_{\text{mem}}}{2P_{cm}}\right)} + \theta_{\min}. \quad (2)$$

90 The Irr_{mem} is calculated based on the past history of irradiance (averaged over the ac-
 91 tively mixed layer), updated at each time step to provide an estimate of the mean day-
 92 time irradiance, which is more important for the optimization than the mean 24 hour
 93 irradiance. Cells also estimate the length of the fraction of the day where irradiance is
 94 above a low threshold, which is called D .

In COBALT we assume that P_{cm} depends on nutrient limitation and temperature according to:

$$P_{cm} = P_{\text{cmax}} \exp(\kappa_{\text{eppley}} T) \text{nutlim}, \quad (3)$$

95 where κ_{eppley} is the temperature scaling factor following Eppley (1972), T is measured
 96 in degrees Celsius, and nutlim is a number between 0 and 1 that depends on nutrient
 97 concentrations and the internal iron quota via Liebig's law of the minimum.

Inorganic nitrogen or phosphorus concentrations, or the internal iron quota, can limit the growth of the small or large phytoplankton, with modeled competition between nitrate and ammonium uptake following O'Neill et al. (1989). COBALT chooses a formulation based on Liebig's Law of the Minimum (von Liebig, 1840), whereby phytoplankton growth rates depend only on the concentration of the most limiting of several different nutrients:

$$\text{nutlim}_{sp,lp} = \min \left((N)_{\text{lim},(sp,lp)}, (PO_4)_{\text{lim},(sp,lp)}, (Fe)_{\text{lim},(sp,lp)} \right), \quad (4)$$

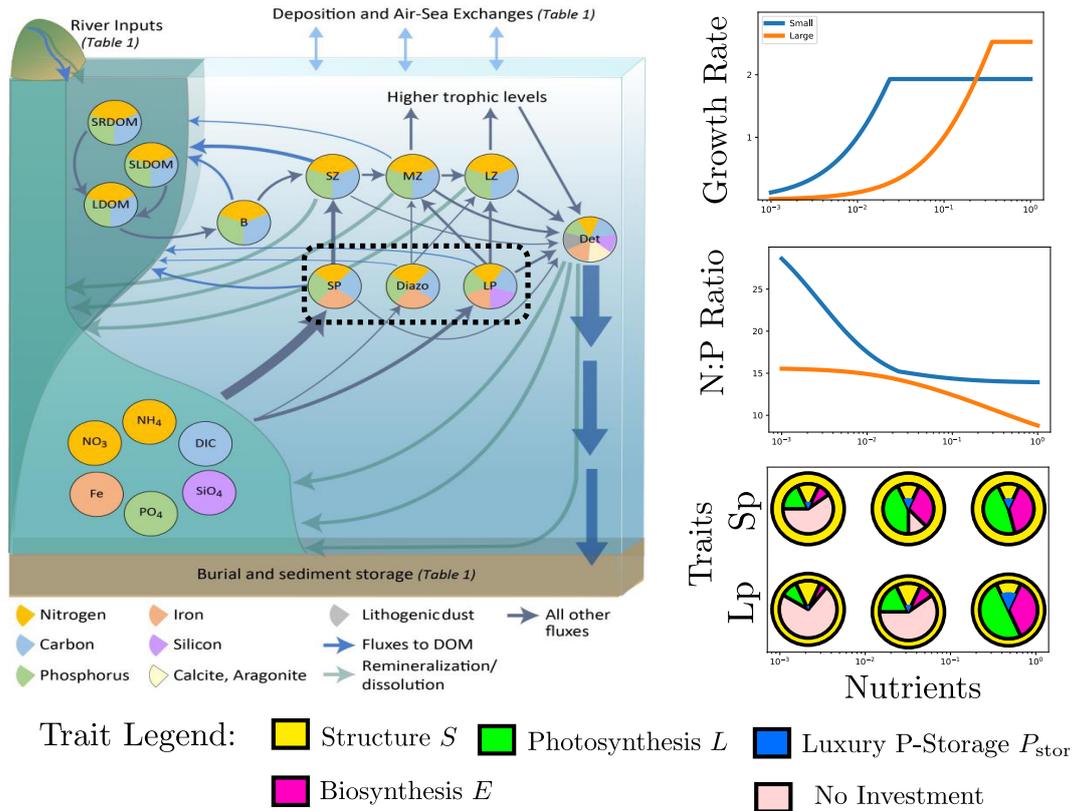

Figure 1: COBALT food web model and modifications to incorporate dynamic stoichiometry and ATOM. The diagram on the left hand-side of the figure shows the COBALT food web model (Stock et al., 2020), illustrating the different tracer pools and the fluxes between them due to food web interactions and biogeochemical dynamics. The pie-charts in the COBALT figure qualitatively indicate the different elements that comprise each pool. A rectangle marks the three phytoplankton pools, which are modeled differently in ATOM-COBALT. The modifications to the large, small, and diazotrophic phytoplankton are described in the far right hand side column, which shows the functional response of large and small phytoplankton to nutrient concentrations (with the x-axis indicating increasing nitrate, ammonium, and phosphate), the response of N:P ratios, and the optimal trait values for low, medium, and high levels of nutrients. The optimal trait-values are shown quantitatively using pie-charts, not to be confused with the pie-charts from the original COBALT figure.

where (suppressing the subscript for now):

$$(\text{PO}_4)_{\text{lim}} = \frac{[\text{PO}_4]}{K_{\text{PO}_4} + [\text{PO}_4]} \quad (5)$$

$$(\text{Fe})_{\text{lim}} = \frac{(Q_{\text{Fe:N}})^2}{(Q_{\text{Fe:N}})^2 + (K_{Q_{\text{Fe:N}}})^2} \quad (6)$$

$$(\text{N})_{\text{lim}} = (\text{NO}_3)_{\text{lim}} + (\text{NH}_4)_{\text{lim}} \quad (7)$$

$$(\text{NO}_3)_{\text{lim}} = \frac{[\text{NO}_3]}{[\text{NO}_3] + K_{\text{NO}_3} + [\text{NH}_4] \frac{K_{\text{NO}_3}}{K_{\text{NH}_4}}} \quad (8)$$

$$(\text{NH}_4)_{\text{lim}} = \frac{[\text{NH}_4]}{[\text{NH}_4] + K_{\text{NH}_4} + [\text{NO}_3] \frac{K_{\text{NH}_4}}{K_{\text{NO}_3}}} \quad (9)$$

$$(10)$$

Diazotrophs fix nitrogen and thus their growth does not depend on nitrogen limitation:

$$\text{nutlim}_{\text{diazotroph}} = \min \left((\text{PO}_4)_{\text{lim,diazotroph}}, (\text{Fe})_{\text{lim,diazotroph}} \right), \quad (11)$$

however, COBALT allows diazotrophs to take up nitrate and ammonium if at sufficiently high concentrations, reducing the contribution of nitrogen fixation to their growth. COBALT defines $(\text{N})_{\text{lim,di}}$ using the same mathematical expression as for other phytoplankton types, and uses it to determine the rate of nitrate and ammonium uptake:

$$J_{\text{up,NH}_4,\text{diazotroph}} = \mu_{\text{diazotroph}} (\text{NH}_4)_{\text{lim,diazotroph}} \quad (12)$$

$$J_{\text{up,NO}_3,\text{diazotroph}} = \mu_{\text{diazotroph}} (\text{NO}_3)_{\text{lim,diazotroph}}. \quad (13)$$

ATOM (Moreno et al., 2018; C. A. Garcia et al., 2020) is a *trait-based* (Litchman & Klausmeier, 2008) phytoplankton model that uses the principle of optimal resource allocation (Shuter, 1979; Smith et al., 2011) to calculate phytoplankton traits- including cell radius, biomass allocations to photosynthesis, biosynthesis, structure, and luxury phosphorus storage (Fig. 1, right side and bottom). These trait values determine modeled phytoplankton cells' functional response to environmental conditions and C:N:P ratio. ATOM models phytoplankton growth rates as limited by the slowest of several different physiological processes: carbon acquisition, nitrogen acquisition, phosphorus acquisition, and biosynthesis. Carbon acquisition depends on the level of light and the biomass allocation to photosynthesis according to the model published in (Talmy et al., 2013), with the exact adaptation to ATOM published in (Moreno et al., 2018) and (C. A. Gar-

110 cia et al., 2020). Nutrient affinity depends linearly on cell radius according to laws gov-
 111 erning diffusion limited uptake (Purcell, 1977), which determines uptake rates of phos-
 112 phate and nitrate/ammonium. Luxury phosphorus storage increases hyperbolically as
 113 a function of environmental concentrations of phosphate. Together, these investments
 114 and the level of luxury storage determine the macromolecular (proteins, lipids, RNA, car-
 115 bohydrates, etc) composition of the phytoplankton cell and therefore its elemental sto-
 116 ichiometry through the ratios of each type of macromolecule.

117 ATOM calculates the trait values by assuming that all phytoplankton cells have
 118 trait values that optimize their growth rate (Shuter, 1979). This (unique) growth opti-
 119 mum occurs at the trait values which make specific biosynthetic, photosynthetic, and ei-
 120 ther nitrogen or phosphorus uptake rates equal. ATOM incorporates the growth rate hy-
 121 pothesis, translation compensation hypothesis, and frugality through the physiological
 122 mechanisms that give rise to these hypotheses (e.g. optimal radius, investment in P-rich
 123 biosynthetic apparatus varies across oligotrophic-eutrophic spectrum, different temper-
 124 ature dependence of physiological processes leads to translation compensation, and lux-
 125 ury storage captures frugality).

126 **2.3 Integration of ATOM Stoichiometry with COBALT**

127 The ATOM-COBALT dynamic stoichiometry model (also referred to herein as sim-
 128 ply the “dynamic model”) introduced here adds the subcellular resource compartments
 129 used in ATOM to each phytoplankton type in COBALT. Compared to COBALT-v2 (Stock
 130 et al., 2020), ATOM-COBALT also adds an additional tracer to each phytoplankton group,
 131 the phytoplankton phosphorus content. ATOM-COBALT models four trait values for
 132 each phytoplankton type, calculating each dynamically from environmental conditions
 133 every time step and using the result to predict the N:P uptake of each phytoplankton
 134 type. Here we model only dynamics of the N:P ratio due to its greater plasticity (Galbraith
 135 & Martiny, 2015) and due to the existence of physiological mechanisms which explain
 136 its variability (Moreno & Martiny, 2018). The traits are allocations of biomass to biosyn-
 137 thesis (E), carbon fixation (F_1), electron transport and light harvesting (F_2), and lux-
 138 ury phosphorus storage P_{stor} . Together, the carbon fixation and electron transport com-
 139 partments form the photosynthesis compartment, defined by $L = F_1 + F_2$.

The units of investments in E and L are specific biomass (Nitrogen per unit Nitrogen). The values thus represent a fraction of the overall biomass dedicated to each purpose. We constrain the maximum total investment in E and L, which decreases with cell radius (therefore different for small, large, and diazotroph) because the cell membrane and associated structures are typically of fixed thickness and thus have a biomass proportional to the surface area, rather than the volume, of the cell (Shuter, 1979; Toseland et al., 2013):

$$S_{sp,lp,diazo} + E + L \leq 1, \quad E \geq 0, \quad L \geq 0, \quad (14)$$

140 where S is the structural investment, and we allow for cells with $E + L + S \leq 1$. Here
 141 $S_{sp,lp,diazo}$ are constant values characterizing each phytoplankton type, while E and L
 142 are dynamical variables updated in each grid cell at each time-step. Allowing this sum
 143 to be less than 1 enables the fixed size classes to exhibit similar responses to those in the
 144 original ATOM model where the radius trait is part of the optimization. This model fea-
 145 ture approximates several different aspects of phytoplankton physiology and ecology, in-
 146 cluding the fixed size classes representing organisms with a range of different cell radii
 147 or cells increasing their surface area to volume ratio.

148 We derive the phytoplankton functional response as a function of the traits, and
 149 assume that phytoplankton make investments in traits that optimize their growth rate
 150 (Shuter, 1979). Because each compartment has a different elemental composition, the
 151 investment in traits will determine the relative uptake of nitrogen and phosphorus, and
 152 therefore the elemental stoichiometry of each phytoplankton type. This allows the trait-
 153 based model to encode the physiological and ecological mechanisms determining phy-
 154 toplankton N:P ratios.

155 To derive the functional response in terms of traits, we assume that cells with a
 156 given set of traits (E, F_1, F_2) grow at the minimum rate implied by three biochemical
 157 processes: nutrient acquisition, macromolecule synthesis, and carbon acquisition.

$$\mu = \min(\mu_{nut}, \mu_{synth}, \mu_{light}) \quad (15)$$

We assume that

$$\mu_{nut} = P_{cmax}nutlim, \quad (16)$$

158 where we calculate nutlim using the same functional response in COBALT: a Michaelis-
 159 Menten function for nitrogen and phosphorus limitation (using (O’neill et al., 1989) to

Table 1: List of model parameters, their definitions, and values. Dynamically calculated trait values appear in the initial rows.

160 capture ammonium and nitrate limitation and uptake) and a functional form based on
 161 the internal iron quota for iron limitation (Eq. 10).

Synthesis limitation depends on the investment in biosynthesis:

$$\mu_{\text{synth}} = P_{\text{cmax}}E, \quad (17)$$

and light limitation on the investments in carbon fixation (F_1) and electron transport (F_2):

$$\mu_{\text{light}} = \frac{P_m \left(1 - \exp \left(-\frac{\alpha \phi_M F_2 \text{Irr}}{P_m} \right) \right) - b_{\text{resp}}}{1 + \zeta}. \quad (18)$$

Here, P_m , the maximum light-limited photosynthesis rate, depends on the investments in F_1 and F_2 (see Tab. 1 for parameter definitions and values):

$$P_m = \min(k_1 F_1, k_2 F_2). \quad (19)$$

162 The investment in electron transport proteins F_2 is analogous to the Chl:C ratio that
 163 determines the growth rates in COBALT and in the original Geider formulation (Talmy
 164 et al., 2013), allowing Chl:C to be calculated from F_2 through multiplication by 0.075
 165 and normalization by the total cellular investment $S + E + L$.

166 For given environmental conditions, we model phytoplankton allocations by assum-
 167 ing growth rate maximization, which occurs when $\mu_{\text{nut}} = \mu_{\text{light}} = \mu_{\text{synth}}$. We show
 168 the full details of this solution procedure in Section S2. It involves solving a nonlinear
 169 equation for the balance between carbon fixation and electron transport proteins (F_1 and
 170 F_2) at fixed total photosynthesis investment L , which leads to a linear equation for the
 171 balance between the overall photosynthesis investment L and the biosynthesis investment
 172 E . We use an offline routine to solve the non-linear equation and approximate it using
 173 a Fourier-Chebyshev series, enabling us to efficiently calculate optimal solutions. To ac-
 174 commodate the diel cycle of irradiance, we adopt an irradiance memory formulation sim-
 175 ilar to that of COBALT where the cell determines the optimal investment in L based
 176 on the history of past irradiance (averaged over the actively mixed layer) and an esti-
 177 mate of the length of the light period, where the optimization assumes constant irradi-
 178 ance during the light period.

179 To calculate phytoplankton N:P we specify the specific N and P content of each
 180 subcellular compartment and add a luxury P-storage compartment to the model. We
 181 denote the nitrogen and phosphorus contents of each compartment with parameters (see

182 Tab. 1). N_S and P_S represent the N and P content of the structure pool in g/g dryWeight.
 183 N_{prot} is the average N-content of proteins, which is equal to the N-content of the pho-
 184 tosynthesis pool because that pool is modeled as containing only proteins. The biosyn-
 185 thesis pool contains a mixture of proteins and RNA, but the N-content of RNA is nearly
 186 equal to that of proteins so that one constant (N_{prot}) is sufficient to describe the N-content
 187 of both pools. The photosynthesis pool does not contain any P . P_E represents the P con-
 188 tent of the biosynthetic pool, and P_{stor} is the content of the storage pool with units of
 189 g/gDryWeight (and hence a dynamic model variable rather than a parameter). Using
 190 these terms, we can calculate the stoichiometry of a cell using the strategy (E, L) and
 191 with luxury storage P_{stor} , by summing the N and P contents of each compartment and
 192 taking the quotient of the result:

$$\text{N:P} = \frac{(SN_S + (E + L)N_{prot}) \text{ MolP}}{(EP_E + SP_S + P_{stor}) \text{ MolN}} \quad (20)$$

193 Here Mol_N and Mol_P are the mass in grams of 1 mole of nitrogen and phosphorus,
 194 respectively. The values of the N and P content parameters and the allocation to the struc-
 195 tural pool S can be derived from cell radius and the macromolecular composition of each
 196 pool, though these compositions are also uncertain. Here we treat the N and P content
 197 parameters of each subcellular compartment as fundamental, tunable parameters in the
 198 model, however, we constrained the choice for these parameters using our knowledge of
 199 their macromolecular composition (which is quantified more explicitly in several papers
 200 (Shuter, 1979; Daines et al., 2014; C. A. Garcia et al., 2020; Sterner & Elser, 2017)). Rel-
 201 ative to the Redfield ratio, the biosynthesis pool is rich in P and the structural and pho-
 202 tosynthesis pool are poor in P.

203 The structure pool S consists of a fraction corresponding to the cell wall; membrane;
 204 and periplasmic space, and also static components of the cytoplasm (such as DNA, RNA,
 205 lipids, carbohydrates, and housekeeping proteins). The cell wall and membrane space
 206 have a fixed thickness, and thus the value of S is inversely proportional to cell radius,
 207 so that $S_{sm} = S_{di} > S_{lg}$. The N content of the structure pool is modeled as the same
 208 for each type, but $P_{S,di} < P_{S,sm} < P_{S,lg}$ to capture the capacity for small phytoplank-
 209 ton to utilize sulfolipids instead of phospholipids in their cell membranes, and the ten-
 210 dency for diazotrophs to be highly efficient at P-utilization, enabling them to reach higher
 211 N:P ratios than other phytoplankton. Phospholipids in small phytoplankton and dia-
 212 zotrophs are modeled as luxury storage of P.

213 Luxury P storage has slightly different parameterizations in large phytoplankton
 214 than in diazotrophs and small phytoplankton. In both cases luxury storage increases hy-
 215 perbolically as a function of phosphate concentrations, but for large phytoplankton the
 216 overall level of storage is scaled by the total investment so that it is proportional to cy-
 217 toplasmic volume:

$$P_{stor,lp} = \frac{P_{stor,max}[P]}{K_{P,stor} + [P]} (S_{lp} + E_{lp} + L_{lp}) \quad (21)$$

218 Here [P] refers to the ambient concentration of phosphate in the environment.

219 For small phytoplankton and diazotrophs, luxury P-storage is parameterized to re-
 220 flect the P-content in phospholipid membranes, which can be substituted for sulfoquinovo-
 221 syl diacylglycerol (SQDG) at low phosphorus concentrations (Van Mooy et al., 2006).
 222 SQDG contains sulfur instead of phosphorus and SQDG substitution reduces phytoplank-
 223 ton P-quotas. We therefore scale the luxury storage term to be proportional to the size
 224 of the structure pool, which is the pool in the cell that contains lipid membranes:

$$P_{stor,sp,di} = \frac{P_{stor,max}[P]}{K_{P,stor} + [P]} S_{sp,di}$$

225 The half-saturation constants for luxury storage, $K_{P,stor}$, are greater than the cor-
 226 responding half-saturation constant for phosphorus limitation of each type, and the pa-
 227 rameter $P_{stor,max}$, which is the maximum possible level of P-storage, varies between the
 228 small and large phytoplankton and diazotrophs (see Table 1). In small phytoplankton
 229 and diazotrophs, these constants correspond to a storage pool represented by membrane
 230 phospholipids and therefore are smaller than the constant in large phytoplankton, which
 231 are known to store much greater quantities of phosphorus and reach much lower N:P ra-
 232 tios in P-rich conditions (Rhee, 1974). The scaling to the level of total investment mod-
 233 erates the level of luxury storage in environments where iron or nitrogen are highly lim-
 234 iting.

235 The N-content of the biosynthesis and photosynthesis pool are assumed to be the
 236 same as that of proteins, reflecting the fact that these pools are primarily proteins and
 237 RNA which have nearly identical N-content. The P-content of biosynthesis pool depends
 238 on the ratio of ribosomes to proteins in the biosynthetic apparatus, which is a free pa-
 239 rameter that controls how strongly N:P ratios change with growth rate. The parame-
 240 ter choice represents an approximate 50% split between ribosomes and other proteins

241 in the biosynthesis apparatus, consistent with other parameterizations (Toseland et al.,
 242 2013) and with fits of the ATOM model to data (C. A. Garcia et al., 2020). Section S2
 243 and Figures 3 and S1 show how the optimal strategies vary globally in numerical sim-
 244 ulations, and how these shifts lead the emergence of model N:P ratios.

The optimal strategy determines the N:P ratio of nutrient uptake, which causes the N:P ratio of phytoplankton to approach that of the optimal strategy:

$$J_{\text{NO}_3} = \mu \frac{\text{NO}_3^{\text{lim}}}{(\text{NO}_3)_{\text{lim}} + (\text{NH}_4)_{\text{lim}}} \quad (22)$$

$$J_{\text{NH}_4} = \mu \frac{(\text{NH}_4)_{\text{lim}}}{(\text{NO}_3)_{\text{lim}} + (\text{NH}_4)_{\text{lim}}} \quad (23)$$

$$J_{\text{PO}_4} = \frac{J_{\text{NO}_3} + J_{\text{NH}_4}}{(\text{N:P})_{\text{opt}}} \quad (24)$$

The P_{cmax} and $bresp$ parameters depend on temperature exponentially through the constant κ_{eppley} , but a new temperature dependence is introduced through κ_{photo} , allowing for exploration of the translation compensation hypothesis:

$$k_1 = k_{1,0} \exp(\kappa_{\text{photo}}T), \quad k_2 = k_{2,0} \exp(\kappa_{\text{photo}}T) \quad (25)$$

245 Here $k_{1,0}$ and $k_{2,0}$ refer to the specific efficiency of the carbon fixation and light
 246 harvesting proteins at 0 degrees Celsius (Table 1). Irradiance has a substantial impact
 247 on the temperature dependence of growth rates because κ_{photo} cancels from the right hand
 248 side of Eq. 18 for small Irr . We illustrate the impact of both irradiance and κ_{photo} on
 249 modeled growth rates and allocations in Section S3.

250 **2.4 Alternative Models**

251 Considerable uncertainty still exists about the relative contribution of the growth
 252 rate hypothesis, translation compensation, and frugality to phytoplankton elemental sto-
 253 ichiometry. In order to explore the potential impacts of each of these mechanisms on bio-
 254 geochemical cycles, we developed a series of alternative models each emphasizing one of
 255 the physiological mechanisms, as well as a static control model used to understand the
 256 magnitude of the effects of using dynamic stoichiometry.

257 ***Static Control Model:***

We developed a static control model which uses the functional response of the ATOM-COBALT dynamic model but maintains the static ratios used by COBALT:

$$(\text{N:P})_{\text{sm}} = 22, \quad (\text{N:P})_{\text{lg}} = 12, \quad (\text{N:P})_{\text{di}} = 40$$

258 This ensures that the differences between the static control and the fully dynamic ATOM-
 259 COBALT model arise because of dynamic stoichiometry rather than differences in other
 260 aspects of the functional response, such as growth rates. Because the functional response
 261 has changed from the standard COBALT implementation (Stock et al., 2020), simula-
 262 tions using the static control model may differ from those using standard COBALT.

Frugal Model: The second alternative is the *frugal model*, again using the same functional response as the ATOM-COBALT model but modeling N:P based on the concentration of phosphate, following (Galbraith & Martiny, 2015):

$$(\text{N:P}) = \frac{1}{3.1 \times 10^{-2} + 4.818 \times 10^4 [\text{PO}_4]}$$

263 In this model small and large phytoplankton and diazotrophs have the same N:P. Fig-
 264 ure 1 illustrates this mechanism through the increase in stored P with phosphate.

Growth Rate Model: The third alternative model is called the *growth rate model* and focuses on the growth rate hypothesis, excluding frugality by setting to a constant the level of luxury-P storage in each of the small, large, and diazotroph types. We modified the models by setting the stored-P equal to a fraction of the maximum in each type:

$$P_{\text{stor}} = 0.3P_{\text{stor,max}}$$

265 Thus the N:P of each type only varies according to the growth rate. In Figure 1, this mech-
 266 anism corresponds to the increase in biosynthetic allocation with increased nutrients and
 267 light.

Dynamic Plus Translation Compensation Model: The final alternative is called the *dynamic plus translation compensation model* (or Dynamic plus Trans. Comp.). Translation compensation occurs when the temperature dependence of photosynthetic and biosynthetic processes differ. In the fully dynamic model we assume these dependencies are the same, but in the translation compensation model we make photosynthetic proteins and pigments temperature independent by setting the exponential constant equal to 0:

$$\kappa_{\text{photo}} = 0.0$$

We also shift the value of the parameters $k_{1,0}$ and $k_{2,0}$ so that they have the same values as they would in the dynamic model at $T = 15$ Celsius, which maintains roughly the same average value of k_1 and k_2 across the two simulations. After this shift, we have:

$$k_{1,0} = 0.37332, k_{2,0} = 0.8568$$

268 This changes both the optimal balance between photosynthetic and biosynthetic invest-
 269 ments (E and L) and the overall functional response of growth rates to temperature. In
 270 the translation compensation model, growth rates will be lower in warm waters and higher
 271 in cold waters compared to the fully dynamic model, assuming identical environmental
 272 conditions. However, due to the form of Eq. 18 for the photosynthetic functional response,
 273 the impact of temperature on growth rates becomes irradiance dependent, so that even
 274 in the dynamic model there is a translation compensation effect under low irradiance con-
 275 ditions. Section S3 explores these issues in more detail.

276 **Observational Data**

277 We gathered datasets from 36 different cruises and long-term time series sites that
 278 contained measurements of the N:P of particulate organic matter in the surface ocean
 279 (Table S1). To avoid biases induced by highly variable sampling frequencies between dif-
 280 ferent cruises, we binned samples from the top 100m sampled on the same day. Selected
 281 cruises provide coverage of most ocean regions and biomes, and the majority of data comes
 282 from recent, intensive GO-SHIP expeditions (Tanioka, Larkin, et al., 2022).

283 **Numerical Experiments**

284 We embedded the static control model, the dynamic model, and each alternative
 285 model within a series of ocean-ice-ecosystem retrospective simulations using the GFDL
 286 Modular Ocean Model 6 (MOM6) and Sea Ice Simulator 2 (SIS2), using a nominal 0.5°
 287 horizontal grid spacing (OM4p5 (Adcroft et al., 2019)). The vertical grid uses 75 ver-
 288 tical layers in hybrid z^* -isopycnal coordinates implemented through an Arbitrary Lagrangian-
 289 Eulerian method that applies the z^* coordinate near the surface and the isopycnal co-
 290 ordinates in the ocean interior. The ocean and ice model configurations match those within
 291 the fully-coupled ESM4.1 model (J. Dunne et al., 2020). Model simulations were forced
 292 using the Common Ocean-Ice Reference Experiment II (Large & Yeager, 2009), a 60-year
 293 dataset representing atmospheric forcings from 1948 to 2007. Initial conditions were cho-

294 sen similar to the fully coupled model (Stock et al., 2020): from World Ocean Atlas 2013
295 (WOA13) data for temperature, salinity, oxygen, and dissolved inorganic nutrients (H. E. Gar-
296 cia et al., 2013; H. Garcia et al., 2014), and from the Global Ocean Data Analysis Project
297 (GLODAPv2) for dissolved inorganic carbon and alkalinity (Lauvset et al., 2016). Ini-
298 tial conditions for other tracers were derived from outputs of a previous version of COBALT
299 (Stock et al., 2014), and initial conditions for additional tracers corresponding to small,
300 large, and diazotroph phosphorus were derived based on assumed constant ratios in each
301 pool. We specify external nutrient fluxes including atmospheric NH_4 and NO_3 deposi-
302 tion (Horowitz et al., 2003), Fe deposition from dust (Zhao et al., 2018) using Baker and
303 Croot to calculate Fe solubility. Coastal Fe and river nutrients derive from the Global-
304 NEWS dataset (Seitzinger et al., 2005), following the prescription in Stock et al.. Five
305 model simulations captured 60 years of ocean dynamics, the reported results come from
306 climatology computed from the last 20 years of each simulation.

307 **Biogeographic Analysis**

308 We defined ocean biomes for biogeographic analyses by dividing the surface grid
309 points from numerical simulations into four bins based on latitude and chlorophyll con-
310 centrations. The biomes correspond to the subpolar ocean (above 45N/S), mid-latitude
311 (between 23.5N/S and 45N/S) high chlorophyll, tropical (between 23.5S and 23.5N) high
312 chlorophyll, and oligotrophic (below 45N/S and low chlorophyll), and are calculated sep-
313 arately for each simulation. For observational data, we set the boundary between high
314 and low chlorophyll to a surface concentration of $0.125\text{mg}/\text{m}^3$, following the definition
315 in (Polovina et al., 2011). Due to variations in the food web structure in the static and
316 dynamic models, we selected distinct chlorophyll thresholds for each model so that the
317 total area of high and low chlorophyll areas match the biome definitions in (Polovina et
318 al., 2011).

319 We classify nutrient limitation by comparing the Liebig factors (see Eq. 10) for N,
320 P, and Fe limitation in small phytoplankton (and P and Fe for diazotrophs), weighted
321 by productivity to de-emphasize winter periods in polar regions where nutrient limita-
322 tion isn't meaningful. Strong limitation implies that one of the nutrients is substantially
323 more limiting than the other two (a difference of Liebig factors of more than 0.2), and
324 weak limitation means either that two or more nutrients are very close to equally lim-
325 iting, or that the Liebig factor is quite close to 1.

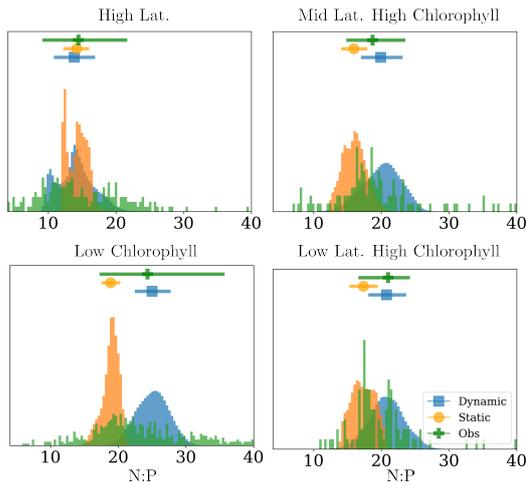

Figure 2: Histograms of N:P of exported particulate organic carbon from the ATOM-COBALT dynamic model, static control model, and observational data at grid points binned by latitude and chlorophyll, with bins chosen to sort grid points and observational data according to ocean biome.

3 Results

3.1 Overall Model Results and Latitudinal Patterns of N:P

The ATOM-COBALT simulation with dynamic stoichiometry produced a mean global N:P value of 21 (spatial average of N:P of export), with a middle 66th percentile range of 16.8 to 26.4, consistent with observations (Martiny et al., 2014; Tanioka, Larkin, et al., 2022), see Table 2 and Fig. 2. N:P ratios exhibited a strong spatial pattern, with low ratios in high-export regions and high ratios in low-export regions, so that the ratio of total N-Export to total P-Export was 16.4 in the dynamic stoichiometry simulations, consistent with the Redfield ratio (Fig. 5). Global NPP and total export out of the top 100m were also within range, at $53.0PgC/yr$ and $8.2PgC/yr$, respectively, consistent with observational constraints (Behrenfeld et al., 2005; Kulk et al., 2020; J. P. Dunne et al., 2007).

ATOM-COBALT simulations with dynamic stoichiometry produce N:P ratios with more variability than the static control (Figs. 2 and 4A), exhibiting greater consistency with observed stoichiometric variations across ocean biomes. Simulations with dynamic stoichiometry produced geometric mean N:P ratios that were on average over 30% higher than static controls in the subtropical gyres (25.0 versus 18.9, observations are 24.4) and

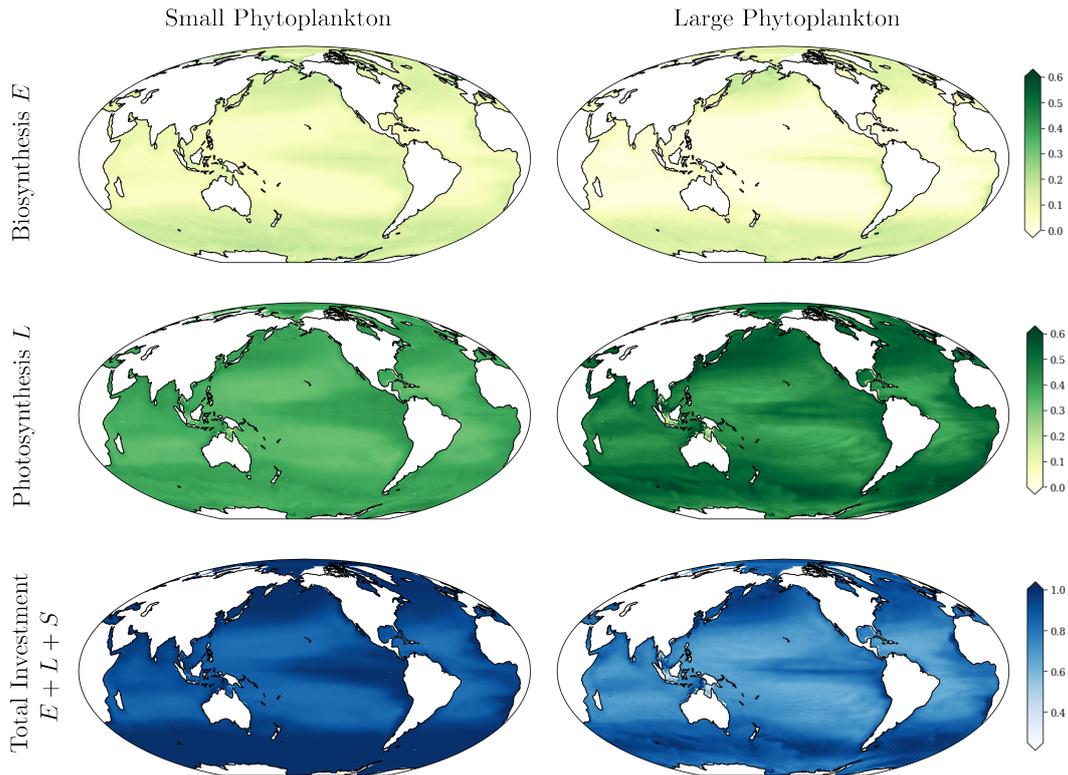

Figure 3: Biomass and productivity weighted average of biosynthesis, photosynthesis, and total investment trait values in small and large phytoplankton.

343 20% higher in the high-chlorophyll tropics (20.7 versus 17.4, observations are 20.4), and
 344 21% higher in the mid-latitude high-chlorophyll regions (19.5 versus 16.1, observations
 345 are 19.0), with nearly equal values in the high-latitudes (13.8 versus 14.2, observations
 346 14.2). Outside of the subpolar oceans, where both models had similar mean N:P, the dy-
 347 namic model was closer to observational data. The dynamic model produced a much larger
 348 range of values than the static model, both within and across biomes, though neither model
 349 had as variable a distribution as the observations.

350 The strong latitudinal gradients in N:P ratios in the dynamic model reflect the global
 351 patterns of traits (Figure 3), which show increasing investments in E, L, and S+E+L mov-
 352 ing from the center of oligotrophic gyres outwards towards more eutrophic areas (Fig.
 353 3). In low nutrient ecosystems, the structure pool dominates the P-quota, with greater
 354 contributions from biosynthesis and storage in eutrophic and high latitude regions. Both
 355 the growth rate hypothesis and the frugality hypothesis thus drive the observed N:P ra-
 356 tios in the dynamic model.

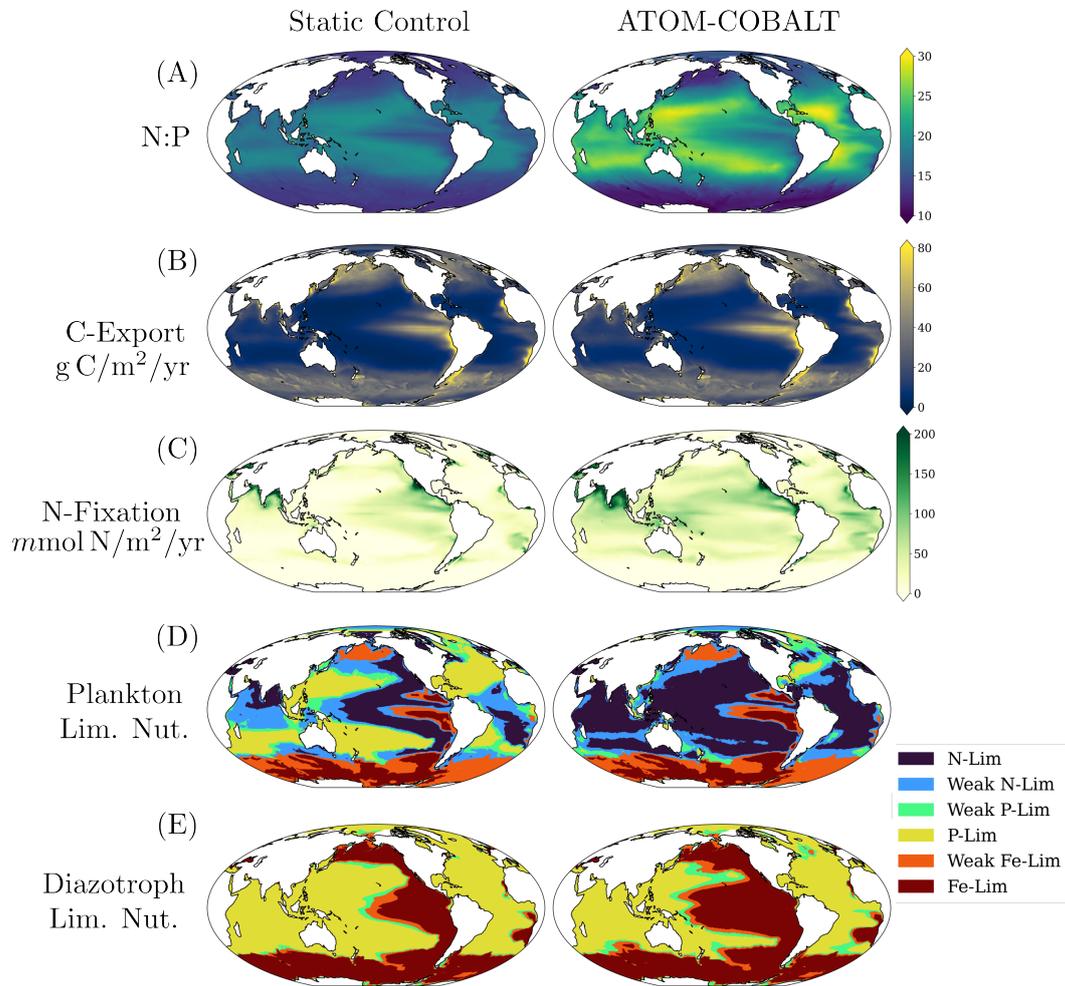

Figure 4: Last 5 years of simulation results from the static and dynamic models, comparing N:P of exported particulate organic matter, total exported particulate organic carbon, water column nitrogen fixation, and nutrient limitation of small phytoplankton and diazotrophs.

Measure	Static Control	Dynamic	Obs.
NPP <i>PgC/yr</i>	46.9	53.0	38.8-52.1 (Behrenfeld et al., 2005; Kulk et al., 2020)
Export <i>PgC/yr</i>	7.5	8.2	5.8-12.9 (J. P. Dunne et al., 2007)
Export N:P	17.3 (15.0, 19.5)	21.0 (16.8,26.1)	20.9 (13.9, 31.4) (Martiny et al., 2014) (Tanioka, Larkin, et al., 2022)
Plankton Nut. Lim.	(0.41 N, 0.23 Fe, 0.36 P)	(0.68 N, 0.24 Fe, 0.08 P)	
Diazotroph Nut. Lim.	(0.37 Fe, 0.63 P)	(0.49 Fe, 0.51 P)	

Table 2: Global Net Primary Productivity, Carbon Export, and N:P of exported organic matter (geometric mean of annually averaged N:P at each grid-cell).

3.2 Biogeographic Comparison Between Dynamic and Static Simulations

Considering patterns of nutrient limitation, the introduction of dynamic N:P stoichiometry substantially reduced large areas of phosphorus limitation that arose in the static-control (see Figure 4B and C, and the ESM4.1 simulation with similar settings (Stock et al., 2020)). In the dynamic simulations, N-limitation occurs throughout the North and South Pacific subtropical gyres and the eastern half of the tropics, in the entire Indian Ocean, and most of the Atlantic Ocean, with the exception of the boundary between the North Atlantic subtropical gyre and the high-latitude North Atlantic, which is weakly P-limited. Fe-limitation occurs in the traditional High-Nutrient Low-Chlorophyll (HNLC) regions. On the other hand, static simulations show large areas of P-limitation, particularly near anthropogenic N-inputs or other regions where nutrient supply is enriched with N relative to P, such as the entire North Atlantic subtropical gyre and transition zones between the Indian and South Pacific subtropical gyres and the Southern Ocean. Overall, there is an 79% decrease in the areal extent of P-limitation from 36% in the static control to 8% in the dynamic ATOM simulation. A smaller decrease of P-limited areas occurred for diazotrophs, by 20% from 75% in the static controls to 61% in the dynamic simulations, restricting to latitudes lower than 40° where most N-fixation occurs. In the static simulations, very little Fe-limitation occurs in the subtropical gyres, in contrast to the dynamic simulations where parts of the North and South Pacific subtropical gyres have Fe-limited diazotrophs. The greater range of N:P ratios in the fully dynamic sim-

377 ulations increases the N:P supply threshold at which phytoplankton switch from N to
378 P limitation.

379 The reduction in P-limited areas evident in Fig. 4B and C is accompanied by an
380 enhancement in nitrogen fixation (Fig. 4D) in the dynamic simulations. Nitrogen fix-
381 ation can occur in ecosystems where the phytoplankton in the surface primarily expe-
382 rience N-limitation. N-limitation usually implies that P and Fe are sufficiently replete
383 to support a niche for diazotrophs. A portion of the fixed nitrogen is recycled and makes
384 further contributions to the productivity of the ecosystem. This surface source allows
385 the N:P ratio of export to exceed the N:P ratio in the nutrient supply from deep waters.
386 Consistent with the observation that the fully dynamic model had reductions in areas
387 of P-limitation, overall nitrogen fixation in this simulation was approximately 100% higher
388 than in the static controls, 171 Tg N/yr compared with 90 Tg N/yr. This increase brings
389 predictions more closely in line with observations (Table 3). We observed this broadly
390 across low-latitude regions, including the tropical and subtropical Atlantic, the Indian
391 Ocean, and the Western Pacific. In total, the overall increases in N-fixation in subtrop-
392 ical gyres was 170% and in tropical and low-latitude coastal ecosystems was 70%. A de-
393 crease in N-fixation compared with the static simulations occurred in the HNLC East-
394 ern Equatorial Pacific (see also Fig. 7A).

395 Dynamic stoichiometry caused an increase in export, driven primarily by the re-
396 laxation of P-limitation of diazotrophs and phytoplankton in the subtropics and trop-
397 ics (Fig. 4E). The change in export roughly parallels the changes in both N:P ratios and
398 nitrogen fixation, suggesting that a shift to higher N:P and the resulting increase in ni-
399 trogen availability from diazotrophs explains increases in export. Overall, export increased
400 by 10% in the dynamic simulations compared to control, driven by a 14% increase in the
401 tropical and low-latitude coastal ecosystems and a 30% increase in subtropical gyres, bring-
402 ing estimates from ATOM-COBALT more in line with observations (Emerson, 2014).

403 **3.3 Biogeochemical Fingerprints of Stoichiometry Drivers**

404 Comparison between the dynamic simulation and the alternative stoichiometry model
405 simulations revealed the biogeochemical imprint of each modeled physiological mecha-
406 nism influencing N:P ratios (Figs. 5-8). Three fundamental patterns emerged: (1) fru-
407 gality decreases P-limitation more strongly than the growth rate hypothesis mechanism,

Table 5: Global fractions of nutrient limitation of phytoplankton and diazotrophs in the static control model, dynamic model, and all alternative models.

408 driving comparatively higher N-fixation and export; (2) the Growth Rate Hypothesis mech-
 409 anism produces stronger gradients in N:P between eutrophic coastal and tropical regions
 410 and oligotrophic subtropical regions, which has a large impact on nitrogen fixation pat-
 411 terns; and (3) the dynamic model with translation compensation causes little change in
 412 the N:P ratio and other large scale biogeochemical patterns compared to the dynamic
 413 model.

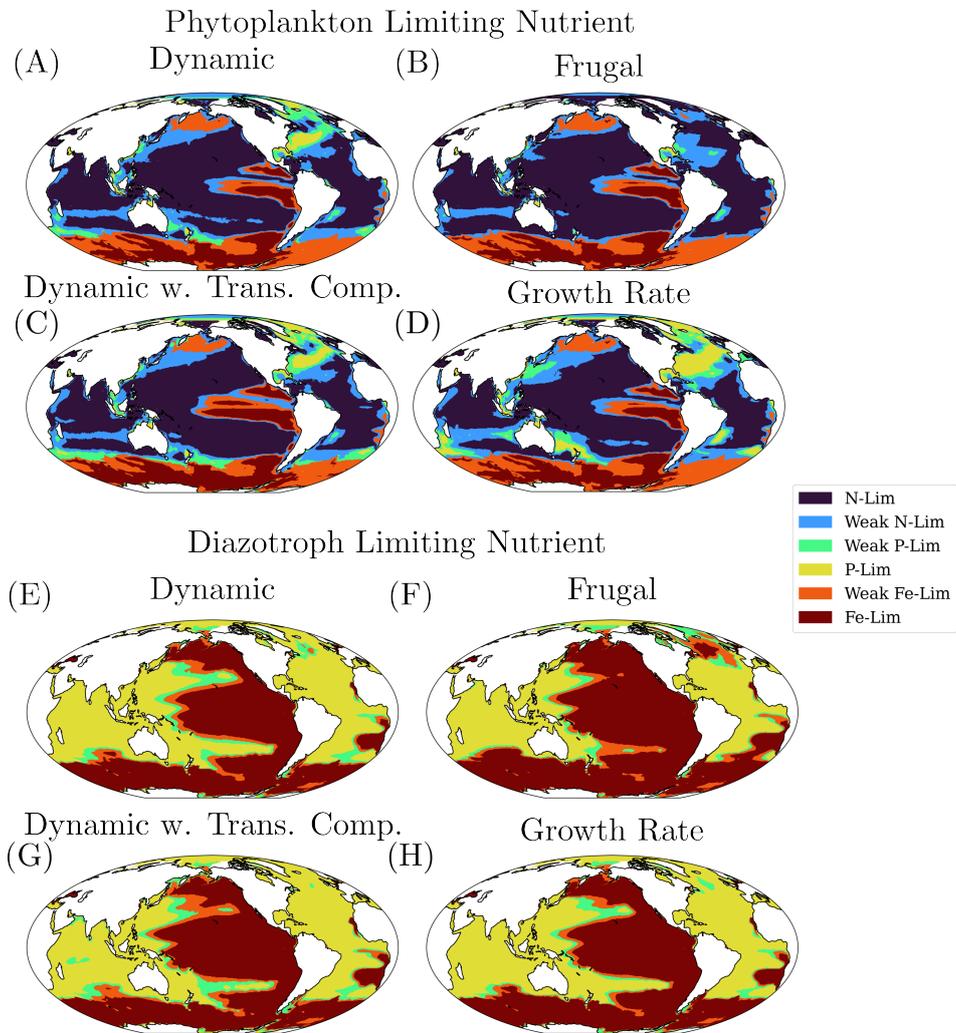

Figure 6: Nutrient limitation of primary productivity in small phytoplankton (top half) and diazotrophs (bottom half), across all dynamic model simulations. Right hand column shows global areal extent of different types of nutrient limitation.

414 All dynamic stoichiometry models produced qualitatively similar “first order” bio-
415 geographic patterns, with elevated N:P in oligotrophic gyres and reduced N:P in high-
416 latitude and productive mid- and low-latitude regions (Figure 5 and Table 4). The growth
417 rate model and frugal model, however, exhibited distinct second order patterns (Figure
418 5B and D). The frugal model shows weaker gradients in N:P across low and mid latitude
419 ecosystems, but has the largest shift from the mid to high latitudes, reflecting patterns
420 of phosphate concentrations. In the growth rate model (and also the dynamic and dy-
421 namic with translation compensation models, which incorporate the growth rate hypoth-
422 esis), the growth rate mechanism enhances N:P contrast between oligotrophic and eu-
423 trophic ecosystems, but has a weaker impact in high-latitude ecosystems. Figure S4 di-
424 rectly shows the difference in N:P ratios between the frugality and growth rate models.
425 The frugal model produces higher N:P in oligotrophic gyres and in productive regions
426 without excessive P, primarily productive regions that are not HNLC. The growth rate
427 model has higher N:P ratios in HNLC areas, where luxury-P storage is at it’s greatest.
428 The dynamic model and the dynamic model with translation compensation implement
429 both the growth rate and frugality mechanisms and show both greater and more con-
430 sistent N:P gradients between biomes than either the growth rate or frugal model. All
431 models produce higher N:P ratios than the static control in low- and mid-latitude biomes,
432 but in the high-latitudes biome the N:P ratios of all alternative models are closer to the
433 controls and the static and translation-compensation model have lower N:P.

434 These shifts in N:P ratios across models drive divergent biogeochemical outcomes:
435 N-fixation (Fig. 7) and export (Fig. 8) increase in all alternative models, with the largest
436 increase in the frugal model and the smallest in the growth rate model. Nitrogen fixa-
437 tion increased by 100% in the dynamic model, 85% in the growth rate model, 153% in
438 the frugal model, and 110% in the translation compensation model (Table 3). Carbon
439 export followed trends in nitrogen fixation, increasing by 0.74 PgC/yr in the dynamic
440 and growth-rate models, 1.13 PgC/yr in the frugal model, and 1.05 PgC/yr in the trans-
441 lation compensation model (Table 6). The magnitude of nitrogen fixation in each sim-
442 ulation corresponds to the magnitude of N:P ratios, and in particular the frugal model
443 generated both high N:P ratios and high nitrogen fixation rates in low- and mid-latitude
444 productive regions, suggesting that P-sparing caused in ecosystems where P is low but
445 non-limiting increases the niche size for diazotrophs. Conversely, less efficient P-utilization

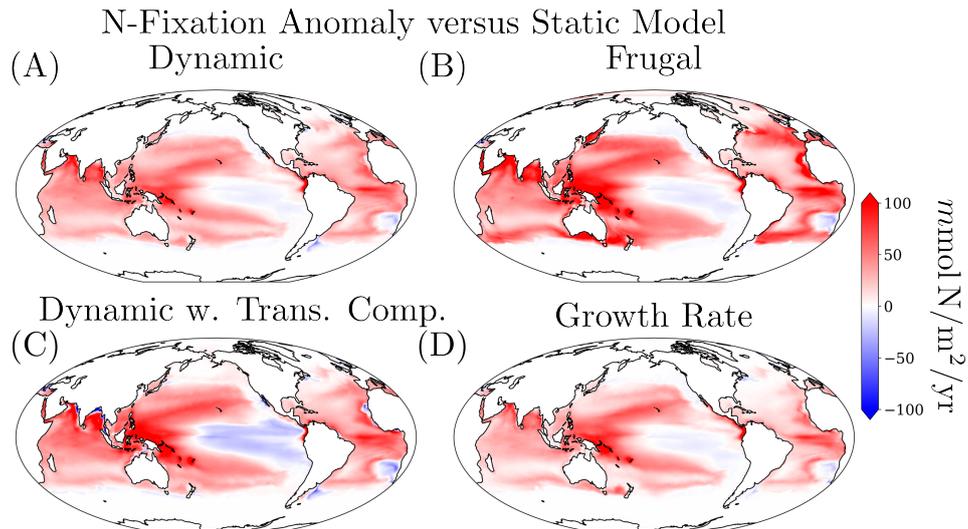

Figure 7: Differences between water column nitrogen fixation rates in dynamic model simulations and the static model averaged over the last five years of simulations. Right hand column shows globally integrated anomalies.

446 in the growth-rate model decreases nitrogen fixation in the low-P Atlantic and Indian
 447 oceans as well as the western Pacific subtropical gyre.

448 Higher N:P ratios (partially mitigated by increases in N-fixation) manifested in de-
 449 clines in the areal extent of P-limitation across the simulations for bulk phytoplankton
 450 where the area declined from 30% in the static model to 8% in the dynamic model, 12%
 451 in the growth rate model, 2% in the frugal model, and 10% in the dynamic with trans-
 452 lation compensation model (Fig. 6). Diazotroph nutrient limitation patterns also shifted,
 453 declining from 63% P-limited in the static control to 51% in the dynamic model, 51%
 454 in the growth rate model, 39% in the frugal model and 49% in the dynamic with trans-
 455 lation compensation model. N:P dynamics due to both growth rate and frugal P utiliza-
 456 tion drove large declines in P-limitation, but the suppression of P-limitation in the fru-
 457 gality model was strongest, due to decreased P-export in ecosystems with low but non-
 458 limiting P in those simulations.

459 The dynamic model with translation compensation caused quantitatively similar
 460 biogeographic patterns to the dynamic model, despite the two models predicting strongly
 461 different N:P ratios across a temperature gradient in otherwise static environmental con-
 462 ditions (Fig. S3). Translation compensation causes the optimal ratio of biosynthetic to

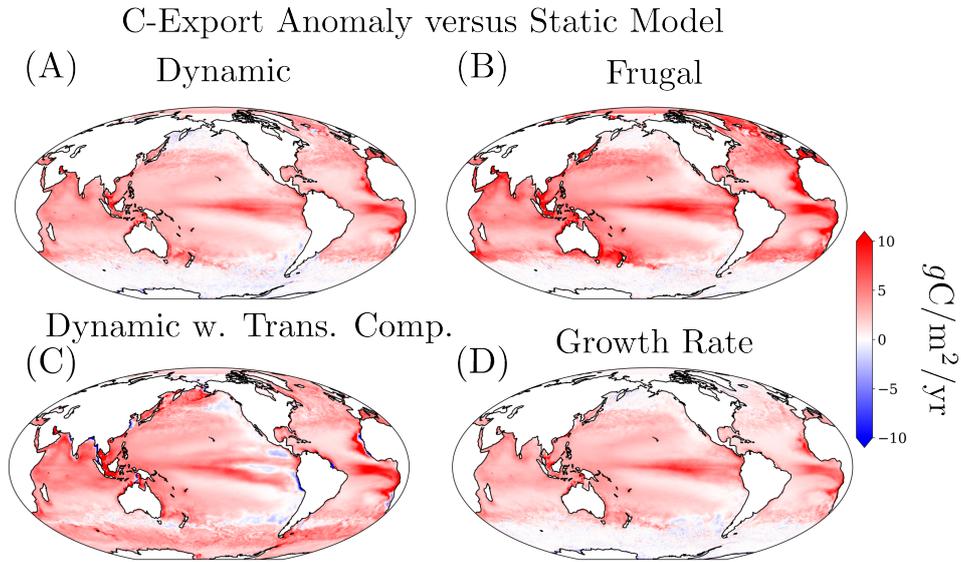

Figure 8: Differences between carbon export between dynamical model simulations and the static model averaged over the last five years of simulations. Right hand column shows globally integrated anomalies.

Model	Global Export (PgC/yr)
Static Control	7.5
Dynamic	8.2 (0.7)
Growth Rate	8.2 (0.7)
Frugal	8.6 (1.1)
Dynamic w. Trans. Comp.	8.5 (1.0)

463 photosynthetic machinery (E:L) to decrease with temperature (Eqns. S2 and S4), mak-
464 ing N:P increase with temperature. However, translation compensation also reduces the
465 temperature dependence of phytoplankton maximum growth rates due to the decreased
466 E:L at higher temperatures, which leads to smaller investments in E at maximum growth
467 rates. This resulted in interactive effects which decreased the impact of temperature on
468 realized N:P, N-fixation, and export. We explore this effect in greater detail in Section
469 S3 and revisit in the Discussion.

470 **4 Discussion**

471 Here we showed that nutrient cycles and biogeochemical processes depend sensi-
472 tively on phytoplankton elemental stoichiometry. Phytoplankton N:P determines how
473 strongly phytoplankton couple elemental cycles, influencing nutrient controls on phyto-
474 plankton growth, N-fixation, and ultimately export. The ATOM-COBALT dynamic model
475 simulations exhibited reduced P-limitation and increased N-fixation rates, supporting
476 the potential for more widespread implementation of dynamic stoichiometry to improve
477 the representation of these processes in ESMs. The dynamic model allowed for greater
478 variation of N:P, decreasing P-utilization across low-latitude regions, and in particular
479 P-deplete regions such as the subtropical North Atlantic or coastal regions near high an-
480 thropogenic N-inputs, leading to a decline in P-limitation and greater availability of P
481 for diazotrophs. Resource ratio theory and the Redfield paradigm suggest that when the
482 N:P of inorganic nutrient supply is lower than the N:P of phytoplankton, there is a niche
483 for diazotrophs which add new N and deplete available P (Lenton & Watson, 2000). Higher
484 N:P in oligotrophic ecosystems therefore increases the size of the niche for diazotrophs,
485 causing increased N-fixation and ultimately export compared to static models.

486 Phytoplankton frugality, the growth rate hypothesis, and translation compensa-
487 tion each provide a physiological mechanism that quantitatively explains observed N:P
488 ratios (Galbraith & Martiny, 2015; Yvon-Durocher et al., 2015; Klausmeier et al., 2004),
489 however, these mechanisms can also cause ecosystem functions to have different sensi-
490 tivity to environmental drivers and lead to different biogeochemical outcomes. Our sim-
491 ulations comparing the alternative models elucidated the specific impacts of each mech-
492 anism. The frugality and growth rate models respond differently to concentrations of non-
493 limiting nutrients. Non-limiting nutrient concentrations do not impact growth rate and
494 thus have no effect on the contribution of the growth rate hypothesis to N:P in any model.

495 On the other hand, the frugality mechanism causes N:P to increase whenever P decreases,
496 whether or not P limits phytoplankton. This resulted in more P-availability in the fru-
497 gality model, and less in the growth rate model, decreasing P limitation and increasing
498 both N-fixation and carbon export in the frugality model compared with all other mod-
499 els.

500 Although the growth rate and frugality hypotheses produced qualitatively similar
501 biogeographic patterns, the enhanced N:P ratios that occur in productive ecosystems in
502 the frugal model caused large differences in N-fixation patterns and both total N-fixation
503 and C-export. N:P observations cannot yet fully disentangle these distinct mechanisms,
504 and models using frugality (or other single factors) alone can reproduce the lowest or-
505 der global distribution of N:P ratios when fit to data. Our simulations provide some ev-
506 idence that the frugal model is partially aliasing stoichiometric patterns driven by vari-
507 ations in N:P ratios driven by the growth hypothesis, and the high N:P produced by the
508 frugal model in low- and mid-latitude eutrophic ecosystems and the sub-polar North At-
509 lantic suggest that the growth rate hypothesis is needed to fully capture the dynamics
510 of phytoplankton N:P and their implications for biogeochemistry. More observations of
511 N:P and comparisons with simulation are needed to fully resolve this issue.

512 Several studies have identified a positive relationship between temperature and phy-
513 toplankton N:P (Martiny, Pham, et al., 2013; Yvon-Durocher et al., 2015), leading to
514 suggestions that temperature driven changes in N:P will moderate expected declines in
515 export in response to anthropogenic warming (Moreno et al., 2018; Martiny, Hagstrom,
516 et al., 2022). Adding translation compensation to the dynamic model showed only very
517 modest shifts in N:P and export. The deviation of the dynamic model with translation
518 compensation simulation from our expectations based solely on N:P ratios may have been
519 caused by shifts in the functional response of phytoplankton to temperature under trans-
520 lation compensation.

521 In the dynamic with translation compensation model, the kinetics of the photo-
522 synthetic machinery does not change with temperature, (achieved by setting $\kappa_{photo} =$
523 0), which leads to cell growth rates exhibiting a flatter temperature dependence than in
524 dynamic model (see Fig. S2), because the rate coefficients of both the biosynthetic and
525 photosynthetic compartments contribute to the overall cell growth rate. This altered de-
526 pendence increases the competitive abilities of phytoplankton in cold waters and decreases

527 them in warm waters, with the discrepancy between the two models greatest when light
528 and nutrients are abundant. The increased growth rate of phytoplankton in cold waters
529 caused the translation compensation model to generate higher export from high-latitude
530 ecosystems despite the reduced N:P ratios there. Thus, the contrasting effect of trans-
531 lation compensation on growth rates and N:P make it unclear what how this mechanism
532 would affect biogeochemistry in a warmer or colder ocean (e.g. under anthropogenic warm-
533 ing or a glacial/interglacial transition), which are important questions that requires fur-
534 ther study. The outcome of the dynamic with translation compensation model also shows
535 the importance of using mechanistic models within self-consistent, biogeochemical sim-
536 ulations, as the result was dependent on how the temperature dependence of biochem-
537 ical processes in the cell impact different organism level functional responses (for exam-
538 ple comparing to the box-model based studies of translation-compensation in Moreno
539 et al. (2018)).

540 Our simulations are consistent with both field observations that show mean phy-
541 toplankton N:P ratios (21:1 (Tanioka, Larkin, et al., 2022)) exceed the traditional Red-
542 field ratio and global hydrographic observations which show that below the surface ni-
543 trate and phosphate concentrations scatter around a 16:1 regression line (Sarmiento &
544 Gruber, 2006). Although N:P ratios exceed Redfield throughout most of the ocean, ex-
545 port in the ocean is skewed to regions with lower N:P ratios which causes the ratio of
546 total exported PON to total exported POP to fall below the mean N:P of phytoplank-
547 ton. It has been hypothesized (Redfield, 1958; Tyrrell, 1999) that the Redfield ratio is
548 an optimal or even fundamental aspect of phytoplankton physiology, leading to home-
549 ostatic control of marine nitrogen cycling, but observations showing a significant devi-
550 ations away from this ratio (Martiny, Pham, et al., 2013; DeVries & Deutsch, 2014; Teng
551 et al., 2014; Tanioka, Larkin, et al., 2022) suggests that the emergence of the Redfield
552 ratio and the ultimate regulation of the nitrogen cycle is more complex.

553 The qualitative distribution of macronutrients and nitrogen fixation of the dynamic
554 N:P simulation are analogous to that of TOPAZ, the biogeochemical model part of GFDL's
555 ESM2M and ESM2G, which included a dynamic N:P formulation (J. P. Dunne et al.,
556 2013). TOPAZ implemented aspects of the growth rate hypothesis through varying al-
557 locations to ribosomes following Klausmeier et al. and elements of frugality through lux-
558 ury phosphorus uptake, only in the large phytoplankton size class. Here, we have sig-
559 nificantly advanced previous formulations by taking advantage of improved global data-

560 sets and understanding of the physiological mechanisms and quantitative allocations that
561 contribute to cellular N:P ratios (Daines et al., 2014; Moreno et al., 2018; C. A. Garcia
562 et al., 2020). While there are numerous differences between TOPAZ and ATOM-COBALT,
563 TOPAZ simulations produced robust global nitrogen fixation levels similar to those seen
564 in our dynamic model. As shown in our results, such a response can emerge from both
565 growth and frugality dynamics, suggesting that the formulation differences do not fun-
566 damentally shift this basic response. Similarly, several other dynamic N:P formulations
567 which use empirical relationships to predict N:P from environmental conditions also achieve
568 comparable large-scale macronutrient distributions, robust nitrogen fixation patterns,
569 and resilience to excess P limitation (Kwiatkowski et al., 2020; Tagliabue et al., 2021;
570 Bopp et al., 2022; Kwon et al., 2022).

571 **4.1 Model Limitations**

572 The ATOM-COBALT model framework has several key limitations. In order to har-
573 monize ATOM and COBALT, we had to simplify ATOM and adapt it to the two size
574 class structure of COBALT. The cell radius trait impacts ATOM's predicted N:P ratios
575 and also enables calculation of a single optimal strategy in all environmental conditions.
576 Predicted N:P in ATOM-COBALT thus depends on both the food-web dynamics, which
577 sets the balance between small and large phytoplankton, but also on the ATOM imple-
578 mentation within each size class which includes an implicit assignment of a cell radius
579 to each type. Model tuning used the original ATOM parameters as a starting point and
580 was adjusted using idealized, zero-D food web simulations to ensure that each size class
581 produced a range of N:P consistent with observations. ATOM-COBALT could be im-
582 proved through a model-fitting procedure that used simulations and incorporated ad-
583 ditional observations beyond N:P ratios, however this is a computationally and concep-
584 tually challenging task that will be taken up in future work. ATOM-COBALT also as-
585 sumes that phytoplankton C:N ratios are static. Greater plasticity of N:P compared with
586 C:N (Sterner & Elser, 2017; Tanioka, Larkin, et al., 2022) and the existence of several
587 mechanistic explanations for N:P variations (Klausmeier et al., 2004; Moreno & Mar-
588 tigny, 2018) provided justification for this assumption. However, systematic C:N varia-
589 tions increasingly appear in observations (Tanioka, Larkin, et al., 2022; Tanioka, Gar-
590 cia, et al., 2022; Martiny, Vrugt, et al., 2013) and C:N variation may be an important
591 biogeochemical driver (Inomura et al., 2022). Assuming static C:N could cause biases

592 compared with observations in certain ocean regions where C:N shows greater variation.
593 For instance, the recent GO-SHIP P18 (Lee et al., 2021), IO9N (C. A. Garcia et al., 2018),
594 and IO7N (Tanioka, Garcia, et al., 2022) expeditions all observed regions of relatively
595 muted N:P variations combined with enhanced C:N variations. Incorporating dynamic
596 phytoplankton C:N requires better understanding of the physiological and environmen-
597 tal drivers behind its variation.

598 **4.2 Global Implications and Conclusions**

599 Our results have implications for our understanding of how the oceans will respond
600 to anthropogenic perturbations such as global warming or eutrophication. Increasing strat-
601 ification is expected to reduce nutrient supplies to the surface ocean, leading to declines
602 in productivity, export, and phytoplankton biomass, which are also predicted to limit
603 the carbon available for higher trophic levels (Bopp et al., 2013). Dynamic N:P provides
604 a mechanism for phytoplankton productivity, biomass, and export to be more resilient
605 to declines in nutrient supply, through the more efficient use of P in oligotrophic ecosys-
606 tems increasing export. We saw this increased resilience in the dynamic N:P simulations
607 where productivity and export were enhanced in the subtropical gyres compared to the
608 static control. These results are consistent with estimates from inverse models (Teng et
609 al., 2014; DeVries & Deutsch, 2014), oxygen utilization in the thermocline (Emerson, 2014),
610 and an emerging perspective of phytoplankton resilience to oligotrophic conditions (Martiny,
611 Hagstrom, et al., 2022). Some model simulations which incorporate greater phytoplank-
612 ton flexibility show a muted (Kwiatkowski et al., 2020; Tagliabue et al., 2021; Bopp et
613 al., 2022) or even reversed (Kwon et al., 2022) (increased NPP under warming) response
614 of the carbon cycle to future conditions. Together, these results suggest that phytoplank-
615 ton adaptation to changing environmental conditions influences ocean biogeochemical
616 dynamics through changes in stoichiometry.

617 The reduction of P-limitation in dynamic simulations could change the sensitiv-
618 ity of the carbon cycle to nutrient additions. Anthropogenic N-inputs can increase pro-
619 ductivity in coastal regions (Rabalais et al., 2002), but in static simulations, particularly
620 with N:P ratios as chosen in ESM4.1, these areas rapidly transition to P-limitation, lim-
621 iting the potential impact on productivity. In dynamic simulations, increases in the N:P
622 ratio allows for N-limitation to persist at much higher resource supply ratios, which may
623 cause more rapid uptake of externally supplied nutrients. Eutrophication of coastal wa-

624 ters and the subsequent expansion of hypoxic and anoxic regions have been a consequence
625 of increased industrialization and are predicted to accelerate in a warming ocean, due
626 to a combination of stratification, reduced oxygen saturation at the surface, and increased
627 respiration in warmer waters (Penn & Deutsch, 2022; Rabalais et al., 2002). By better
628 resolving nutrient limitation patterns, dynamic simulations can improve predictions of
629 how phytoplankton mediate the interactions between eutrophication, deoxygenation, and
630 warming. Declines in P-limitation also extended to diazotrophs in dynamic simulations,
631 leading to a balance between areas of P- and Fe-limitation. Over long time scales, the
632 supply rate of the nutrient limiting diazotrophs exerts strong controls on the nitrogen
633 cycle and ultimately primary productivity (Redfield, 1958). Phytoplankton N:P helps
634 determine these nutrient limitation patterns and thus is essential for modeling biogeo-
635 chemistry at global scales. Capturing long-term N-cycle feedbacks has been a challenge
636 in ESMs, and the large increase in N-fixation triggered by dynamic N:P confirms the-
637oretical work suggesting these ratios are critical for modeling the N-cycle.

638 Our findings here reinforce the idea that variations of phytoplankton elemental sto-
