10 **Abstract**

11 This study provides a global analysis of drought metrics obtained from several climatic,
12 hydrologic and ecological variables in a climate change framework using CMIP6 model data. A
13 comprehensive analysis of the evolution of drought severity on a global scale is carried out for
14 the historical experiment (1850-2014) and for future simulations under a high emissions
15 scenario (SSP5-8.5). This study focuses on assessing trends in the magnitude and duration of
16 drought events according to different standardised indices over the world land-surface area.
17 The spatial and temporal agreement between the different drought indices on a global scale
18 was also evaluated. Overall, there is a fairly large consensus among models and drought
19 metrics in pointing to drought increase in southern North America, Central America, the
20 Amazon region, the Mediterranean, southern Africa and southern Australia. Our results show
21 important spatial differences in drought projections, which are highly dependent on the
22 drought metric employed. While a strong relationship between climatic indices was evident,
23 climatic and ecological drought metrics showed less dependency over both space and time.
24 Importantly, our study demonstrates uncertainties in future projections of drought trends and
25 their interannual variability, stressing the importance of coherent hydrological and plant
26 physiological patterns when analysing CMIP6 model simulations of droughts under a warming
27 climate scenario.

28
29 **Keywords:** Climate change, drought projections, CMIP6 simulations, model uncertainty.

31 **1. Introduction**

32 Assessment of future drought projections is at the forefront of scientific debate in the current
33 research on climate, hydrology, agriculture, and ecology. This is simply due to the multiple
34 dimensions of droughts, which cause strong complexity for drought assessment and
35 quantification (Lloyd-Hughes, 2014; Douville *et al.*, 2021). In addition, the strong
36 environmental and socioeconomic implications of drought changes in future climate scenarios
37 adds more complexity to this debate (Van Loon *et al.*, 2016; Xu *et al.*, 2019; Naumann *et al.*,
38 2021).

39 In order to robustly assess future changes in drought severity, we must refer to different types
40 of drought. This is fundamental to properly evaluate the impacts associated with drought in
41 future climates. Generally, the concepts of meteorological drought (precipitation deficits),
42 agricultural droughts(crop failure or yield decrease), ecological droughts (damages in natural
43 vegetation, reduced photosynthesis activity, and carbon uptake and increased plant mortality),
44 and hydrological droughts (reductions in the availability of water in different sources such as
45 reservoir storages, streamflow and groundwater) are used commonly to refer to drought
46 types. These types are largely impacted by different processes and physical and ecological
47 implications (Wilhite and Buchanan-Smith, 2005; Lobell, 2014; Vicente-Serrano *et al.*, 2020b;
48 Douville *et al.*, 2021).

49 In the literature, a wide spectrum of studies characterised drought projections on the global
50 scale using model simulations of various climatic, hydrological, and vegetation variables under
51 different future climates scenarios (e.g. Cook *et al.*, 2014, 2020; Martin, 2018; Luet *et al.*, 2019;
52 Ukkola *et al.*, 2020; Vicente-Serrano *et al.*, 2020a; Zhu and Yang, 2021; Papalexiou *et al.*, 2021;
53 Zhao and Dai, 2021; Ridderet *et al.*, 2022; Zenget *et al.*, 2022). Nonetheless, most of these studies
54 focused on metrics directly simulated by different Coupled Model Intercomparison Projects
55 (CMIP) since they allow to directly evaluate drought impacts on a variety of agricultural,
56 ecological, and hydrological systems (Quiring and Papakryakou, 2003; Hlavinka *et al.*, 2009;

57 Vicente-Serrano *et al.*, 2012; Stagge *et al.*, 2015a; Bachmair *et al.*, 2016, 2018; O'Connor *et al.*,
58 2022).

59 In the literature, the most widely used drought metrics for drought monitoring and impact
60 assessment are synthetic indices that combine precipitation and atmospheric evaporative
61 demand (AED), allowing for a direct quantification of drought severity and drought extent
62 (Vicente-Serrano *et al.*, 2010; van der Schrier *et al.*, 2013; Tomas-Burguera *et al.*, 2020a; Dai,
63 2021), as well as their impacts on ecosystems (Bachmair *et al.*, 2015). For future simulations,
64 different studies analysed drought projections based on these indices, employing ESMs
65 outputs under different future climate scenarios (Dai, 2012; Naumann *et al.*, 2018; Spinoni *et*
66 *al.*, 2020; Vicente-Serrano *et al.*, 2020a; Zhao and Dai, 2022). According to these scenarios,
67 drought severity would increase, mainly as a consequence of the enhanced AED in a warming
68 climate. Nonetheless, some studies suggest uncertainty of using these metrics (e.g. Berg and
69 Sheffield, 2018; McColl *et al.*, 2022). Specifically, the criticisms argue are that these indices are
70 not necessarily representative of the metrics based on water storage (i.e. soil moisture),
71 surface water generation (i.e. runoff) or vegetation activity (i.e. leaf area and net primary
72 production). These arguments would be supported by the notion that hydrological and
73 ecological systems might show different dynamics and responses under future climates (Berg
74 and Sheffield, 2018; Scheff, 2018). Furthermore, CMIP models generate simulations of
75 hydrological and plant metrics, which would make it unnecessary to focus on climate metrics
76 as proxies of drought impacts (McColl *et al.*, 2022). Moreover, drought indices that include
77 AED in their calculations might overestimate drought severity under high-emissions future
78 climate scenarios. This is simply because future increase in AED is likely to be higher than the
79 expected increase in land evapotranspiration (Et) (Roderick *et al.*, 2015a; Milly and Dunne,
80 2016; Scheff, 2018; Yang *et al.*, 2019), which is also determined by water availability.
81 As such, assessments of drought projections based on different drought metrics make it
82 necessary to provide a more complete spatio-temporal comparison of different drought

83 metrics to provide a more robust picture of how drought responds to future climate.
84 Nevertheless, although recent studies have analysed global drought projections based on the
85 latest model outputs from the CMIP6 using different drought metrics (e.g. Cook *et al.*, 2020;
86 Ukkolaet *et al.*, 2020; Liet *et al.*, 2021; Papalexiovet *et al.*, 2021; Zhu and Yang, 2021; Menget *et al.*, 2022;
87 Zenget *et al.*, 2022; Zhao and Dai, 2022), few works assessed the robustness and coherence in the
88 drought metrics under scenarios of high greenhouse gasses (GHG) emissions. Importantly,
89 these studies lacked the opportunity to investigate some drought metrics that are essential for
90 assessing agricultural and ecological droughts. As such, a focus on these gaps may provide new
91 evidence that helps reconcile perspectives or stress uncertainties related to future trends in
92 drought severity. On the other hand, it is necessary to test the robustness of the spatial and
93 temporal consistency among the different drought metrics, which can give indications on the
94 reliability of drought projections. In the pursuit of this background, the objectives of this study
95 are to i) determine future drought projections based a more complete set of drought metrics
96 to date, providing a more complete mosaic of current global studies and ii) determine the
97 spatial and temporal coherence among the different drought metrics in replicating drought
98 severity. Accordingly, the current global assessment can contribute to the arising debate on
99 the robustness of the different drought metrics, providing new evidences on CMIP6 model
100 uncertainties for agricultural, ecological, and hydrological drought projections under a high-
101 emission climate scenario.

102

103 **2. Data and Methods**

104 We employed monthly data of a set of hydroclimatic variables from the CMIP6 experiment
105 (Eyring *et al.*, 2016). These variables included precipitation, runoff, total column soil moisture,
106 leaf area index (LAI) and net primary production (NPP). Data were provided for the historical
107 period (1850-2014) and for the Shared Socioeconomic Pathway (SSP; 5-8.5) from 2015 to 2100.
108 All CMIP6 individuals that secure data for the necessary variables, as well as the period 1850-

109 2100, were considered in our analysis (see Supplementary Table 1). Recalling that the CMIP6
110 outputs are provided in different native spatial resolutions, we interpolated data to a common
111 resolution of $2.5^\circ \times 2.5^\circ$. To assess future projections in drought severity, our decision was
112 made to consider the SSP5-8.5 scenario, which represents the worst possible scenario
113 compared to the historical experiment.

114 The standardised drought indices were computed based on the common data inputs (e.g.
115 precipitation, runoff, total column soil moisture, LAI and NPP). Nonetheless, other indices were
116 computed using a combination of new variables. For example, maximum and minimum air
117 temperatures, relative humidity, wind speed and solar radiation, were used to calculate AED
118 following the Penman-Monteith FAO-56 equation (Pereira *et al.*, 2015). Overall, based on
119 these data and data of Evapotranspiration (Et), we calculated different indices using: i) the
120 difference between precipitation and AED (P-AED), which is a metric that has been widely used
121 for drought assessment since it summarises the balance between the water available in the
122 form of precipitation and the existing AED (Vicente-Serrano *et al.*, 2010; Tomas-Burguera *et al.*,
123 2020a), ii) precipitation minus land evapotranspiration (P-Et), which is considered a long-term
124 water budget and has been accordingly used to assess drought severity in several works (e.g.
125 Padrón *et al.*, 2020), and iii) the difference between Et and AED (Et-AED), which compares the
126 difference between the available water to evaporate and the water demand by the
127 atmosphere (Kim and Rhee, 2016; Vicente-Serrano *et al.*, 2018) and is highly related to plant
128 water stress (Stephenson, 1990). All these drought metrics were transformed into the same
129 standardised units to make robust spatial and temporal comparisons. To fit data distribution, a
130 log-logistic distribution was used , which is capable of standardising different climate and
131 hydrological records under different climate conditions, as being evidenced in earlier works
132 (e.g. Vicente-Serrano and Beguería, 2016; Vicente-Serrano *et al.*, 2020a). The only exception
133 was for precipitation, which was fitted to a Gamma distribution (Stagge *et al.*, 2015b). We
134 tested the goodness of fit of the standardized indices using the coefficient of determination

135 (R^2) of the QQ plots, which compare the empirical probability distribution function (pdf) of
136 each index and the pdf of the standard normal distribution. Results demonstrate that R^2 were
137 almost close to 1 for majority of the world regions (Fig S1), with small deviations among the
138 models (Fig S2) and for specific timescales (e.g. 3-month and 12-month). Afterwards, a second
139 standardisation procedure was carried out independently for each of the 12 monthly series of
140 the indices. To make this standardisation, both the mean and the standard deviation were
141 computed for the reference period 1850-2014. This procedure minimizes the possible impacts
142 of strong trends presented in the analysed variables for future scenarios in the possibility of
143 calculating the drought indices (Vicente-Serrano et al., 2020a). Furthermore, this
144 standardisation allows for a robust spatial and temporal comparability between the different
145 metrics. Accordingly, drought duration and magnitude can be quantified for each time series
146 and for the different indices. Drought events were identified using the run theory (Tallaksen et
147 al., 1997; Fleig et al., 2006), considering a threshold of $z = -1.28$, which corresponds to a 10%
148 probability of a standard normal observation being below that value. For drought event
149 identification, all indices were computed at the 3-month time scale. To analyse the trends in
150 the duration and magnitude of drought events, a linear regression model was fitted as a
151 function of time, and the estimated slope was used to quantify the amount of change over
152 time. The significance of these changes was assessed using the Mann–Kendall test (Kendall,
153 1948; Mann, 1945).

154 We analysed the relationship between the annual indices (computed at 12-month time scale)
155 using the Kendall's rank correlation coefficient, i.e., Kendall's τ coefficient (Kendall, 1938). This
156 coefficient is a nonparametric measure of rank correlation that is more suitable than
157 parametric statistics (e.g. Pearson's linear correlation coefficient) because it accounts for the
158 non-linear relationships between variables.

159 For each grid point, the temporal agreement between the indices (computed at 12-month
160 scale) was assessed by obtaining the percentage of simultaneous occurrence of years in which

161 a pair of indices were below $z=-1.28$, thus producing a 2-dimensional representation of the
162 results. Also, we computed the percentage of grid points where each pair of indices showed z -
163 value below -1.28, resulting in a time series.

164

165 **3. Results**

166 **3.1. Evolution of drought severity based on different metrics**

167 Fig. 1 shows the evolution of the world land surface affected by drought between 1850 and
168 2100. It is computed as the percentage of land grid points below the 5th percentile of each raw
169 (non-standardised) variable. This percentile is computed independently for each month,
170 considering the 1850-2014 reference period. For all the variables, we found an increase in the
171 world land surface impacted by drought from 1850 to 2010, albeit with some considerable
172 spatial differences. Results demonstrate that precipitation, leaf area, and runoff will likely
173 show a small increase of drought severity in future - scenarios. For precipitation-Et and NPP,
174 the increase was mostly intermediate, although a sharp increase in NPP is noted between 2010
175 and 2030, followed by a constant behaviour to the end of the twenty-first century. For
176 precipitation-AED, Et-AED and soil moisture, a remarkable increase is noted at the end of the
177 century. As illustrated in Figs S3 and S4, some variables exhibited important seasonal and
178 regional differences. For example, during the boreal winter season, drought based on NPP, soil
179 moisture, and Et-AED increased. Rather, for precipitation and runoff, irrelevant drought
180 increase was noted from 1850 to 2100. On the contrary, in the boreal summer season, the
181 main drought increase was recorded for precipitation-AED, Et-AED, and soil moisture, with
182 little increase for other variables (e.g. precipitation, runoff, and precipitation-Et).

183 Overall, we noted an increase in the magnitude of drought events that affects large areas of
184 the world in terms of precipitation-AED, Et-AED, and soil moisture, albeit with significant
185 spatial differences (Fig. 2). Interestingly, these three drought metrics showed a high agreement
186 in terms of the areas that are likely to exhibit the highest increase in the magnitude of drought

187 periods, including the Mediterranean region, Central America, northern South America and
188 western South America, West Africa and South Africa. Nevertheless, it can be noted that the
189 areas affected are much larger using Et-AED metric, with almost the entire land showing an
190 increase in drought severity. Meteorological droughts, based on precipitation, showed an
191 increase in drought magnitude in areas of Central and South America, West Africa, South
192 Australia and the Mediterranean region, although this increase is not as high as suggested by
193 other drought indices (i.e. Et-AED, and soil moisture). This pattern was almost similar when
194 considering precipitation-Et, although some areas of South America did not show an increase
195 in drought severity, suggesting that –in specific regions- the increase in drought magnitude can
196 be reduced if Et is included in the calculations. Drought magnitude trends based on runoff
197 showed smaller changes than considering exclusively precipitation, demonstrating that CMIP6
198 models project a less increase in the magnitude of hydrological droughts than in the
199 magnitude of meteorological (precipitation) droughts. LAI did not show an increase in the
200 magnitude of drought events in large areas of the world, except for parts of East Brazil. Thus,
201 the spatial pattern was sparse on the global scale, with strong regional variability and a
202 dominance of no changes or decrease in the magnitude of drought events in some regions
203 (e.g., South America, Southeast Asia, Central Europe, and North America). Notably, the NPP-
204 based assessment showed a strong reinforcement of drought magnitude in the high latitudes
205 of the Northern Hemisphere. Rather, in some areas of Africa, South America and Southeast
206 Asia, a decrease in the magnitude of the drought episodes, based on the NPP, was noted. .
207 Changes in the duration of drought events were almost similar to those of drought magnitude,
208 particularly in terms of spatial patterns and the behaviour of the different drought metrics (Fig.
209 S5).
210 Some drought metrics show high consistency in identifying positive trends in drought
211 magnitude among the different models. Fig. 3 shows the percentage of models showing
212 positive and statistically significant trends in drought magnitude between 1850 and 2100. As

depicted, almost all models defined the same the regions with strong increase in drought magnitude considering precipitation-AED and Et-AED. This agreement was much lower for soil moisture, , even in large regions where the multimodel median values showed an increase in drought magnitude. A representative example is found in southern North America and South Africa, where multimodel medians showed a large increase in drought magnitude, while less than 40% of the models showed a positive and significant trend. In other regions wherea decline in drought magnitude was observed like northern South America or the Mediterranean, the percentage of models showing significant declining trends was roughly 50%, suggesting a strong uncertainty in model projections. Notably, although precipitation, precipitation-Et and runoff showed a drought increase in fewer regions than soil moisture, the consistency of this increase among models seems to be greater. More than 50% of the models suggested a positive and statistically significant increase in drought magnitude in northern South America and Central America, the Mediterranean and southern Africa for precipitation. A similar pattern was evident for vast areas in North and South America, Central Africa, and Central and South Asia when considering P-Et. This suggests that Et projections suppress the trend toward higher drought magnitudes in Southern Africa in comparison to precipitation-based projections, with only few models showing a positive and statistically significant trend. Interestingly, for runoff almost 50% of the models suggested a significant increase in drought magnitude in large regions of the Northern Hemisphere (e.g. Alaska, Labrador, Scandinavia, West Russia), while they did not witness a relevant increase in drought magnitude based on precipitation and precipitation-Et metrics. In the same context, apart from the high latitudes of the Northern Hemisphere, there were no regions where more than 30% of models showed an increase in drought magnitude for the NPP. Interestingly, results demonstrate that drought magnitude based on LAI will not change anywhere worldwide, with almost no model suggests significant changes.

238 Like drought magnitude, similar patterns of drought duration changes were observed globally
239 (Fig. S6), with majority of the models suggesting no significant changes in ecological and
240 agricultural droughts across majority of the world regions under scenarios of high greenhouse
241 gas emissions.

242 The negative trends in drought magnitude (Fig. 4) and duration (Fig. S7) indicated few regions
243 and metrics in which the models agree on a decrease in drought severity, mainly for
244 precipitation in the high latitudes of the Northern Hemisphere. Even for LAI and NPP, the
245 percentage of models that showed a decrease in drought magnitude is low. As depicted,
246 although some areas, based on some metrics, showed a projected decrease in drought
247 duration and magnitude with multimodel medians (e.g. Southeast Asia with LAI, Central Africa
248 with the NPP, West Russia with soil moisture), there is still large inconsistency among the
249 models. In the same context, while a steady increase in drought duration and magnitude was
250 projected for some regions and variables, only few areas witnessed a decrease in drought
251 duration and magnitude, irrespective of drought metric used. Thus, although there are
252 important uncertainties between drought metrics and models related to the increase of
253 drought duration and magnitude, there is a high consistency between models and metrics
254 concerning drought decrease since drought magnitude and duration are not expected to
255 decrease much under a scenario of high greenhouse gasses emissions.

256

257 **3.2. Spatio-temporal relationships among drought metrics**

258 In addition to knowing the consistency of trends between different drought metrics and
259 models, it is also relevant to analyse the consistency of the temporal relationship in the
260 drought severity based on these metrics (Fig. S8). As illustrated, we found strong annual
261 relationships between some pairs of drought indices in the historical period. For example, the
262 correlation was higher than 0.8 between precipitation and precipitation-AED and between
263 precipitation and precipitation-Et in most areas of the world. Also, a high correlation was

264 observed between precipitation-AED and precipitation-Et, with few exceptions, mainly in arid
265 and semiarid regions where correlations decreased. Other pairs of drought metrics showed
266 lower relationships on global scale, with important spatial differences. For example, the
267 relationship between precipitation and Et-AED was only high in water-limited regions, where
268 Et is mostly determined by water availability. It is worth mentioning that the relationship
269 between precipitation (and also between the other climatic metrics) and soil moisture was low
270 in most regions. Thus, the correlation with soil moisture was higher considering precipitation-
271 AED and particularly Et-AED in regions like South America, Africa, and South Asia. LAI and NPP
272 showed high correlations particularly in water-limited and cold regions. Nevertheless, these
273 two ecological variables showed low correlations with the different meteorological drought
274 metrics, suggesting that the interannual variability of agricultural and ecological droughts
275 simulated by models is independent from those of climatic droughts in most regions of the
276 world. This pattern was also observed considering soil moisture, with low correlations found
277 between the interannual variability of soil moisture and the NPP and LAI in most regions,
278 irrespective of biome types and bioclimatic conditions. The relationship between precipitation
279 and runoff was high in most regions of the world, except for North America and most of
280 Eurasia. In contrast, the relationship between interannual variability of runoff and soil
281 moisture tended to be low globally, apart from the Mediterranean, northern South America,
282 and Africa. Similarly, ecological metrics (i.e. NPP and LAI) showed low correlations with runoff
283 worldwide.

284 Overall, these results suggest that, except for the high relationship between different climate
285 metrics and their corresponding spatial differences that are mainly determined by the average
286 water availability and temperature, the temporal relationship between different drought
287 metrics was generally low in most regions of the world. This relationship was particularly low
288 between climatic and vegetation metrics, as well as between soil moisture and other drought
289 metrics.

290 The spatial pattern and the magnitude of the temporal relationships between the different
291 variables did not show important changes considering future simulations (2015-2100), as
292 compared with historical simulations (Fig. S9), albeit with some important exceptions (Fig. 5).
293 For example, the relationship between the interannual variability of precipitation and other
294 climatic drought metrics generally decreased, which is quite relevant in some areas of Central
295 Asia considering precipitation-AED, but also in the Sahel and high latitudes of the Northern
296 Hemisphere considering Et-AED. On the contrary, the relationship between precipitation and
297 precipitation-Et remained stable for both the historical period and future. Also, we found a
298 decrease in the relationship between precipitation-AED and precipitation-Et in some regions of
299 Europe, South America, and Africa. The relationship between LAI and NPP was stable for the
300 historical period and future simulations in most regions, albeit with a trend to reinforce in
301 some regions. In addition, the relationship between precipitation and LAI tended to reinforce
302 in the high latitudes of the Northern Hemisphere. This was also observed with the NPP,
303 although a decline in the correlation between precipitation and NPP was observed in the
304 Mediterranean, southern North America and northern South America. While the relationship
305 between NPP and precipitation-AED was low during the historical period, this relationship was
306 projected to decline further in the future, particularly in arid regions, the Amazon basin, and
307 some wet areas of Africa. The decrease in the relationship with the NPP was even more severe
308 when considering Et-AED, with an overall global decline. In addition, the relationship between
309 NPP and soil moisture is likely to decline over large areas (e.g. the Mediterranean, northern
310 South America, southern Africa, and Australia). Finally, the relationship of the runoff to other
311 drought metrics tended to be stable between the historical period and the future high
312 emission scenario, although a decreasing correlation with precipitation was observed in
313 Scandinavia, and particularly with precipitation-AED and Et-AED in most Africa and the Amazon
314 basin.

315 The temporal agreement in drought conditions among the different metrics is small in most
316 regions during the historical period (Fig S10), suggesting that the annual drought conditions
317 tend to differ noticeably between metrics. There was some agreement in the identified
318 drought periods between precipitation and precipitation-AED, except in arid lands. A similar
319 pattern was also noted between precipitation and precipitation-Et in wet regions and between
320 precipitation-AED and Et-AED in arid lands. Nevertheless, the agreement in the occurrence of
321 droughts between climatic, ecologic, and hydrologic metrics was small. Herein, it is worth to
322 note that while our analysis is restricted to annual droughts to reduce the role of seasonality
323 and the lags in the response of hydrological, agricultural and ecological drought conditions to
324 meteorological droughts and irrespective of the physical consistency among models, drought
325 periods mostly do not coincide in time among the different metrics. For the projected
326 scenario, the temporal agreement between metrics shows some increase (Fig. S11). This is
327 particularly relevant in some regions, such as the Mediterranean region, southern Africa, the
328 Amazon basin, and Central America when comparing drought episodes recorded with
329 precipitation and precipitation-AED, precipitation-Et, Et-AED and soil moisture and also
330 between precipitation-AED and precipitation-Et and between Et-AED and soil moisture,
331 particularly in water-limited regions. The agreement in the temporal identification of drought
332 conditions also increases when comparing the climatic indices and the runoff in some areas,
333 particularly in the Amazon and the humid regions of Africa, suggesting an agreement in annual
334 droughts between some pairs of drought metrics, especially in water-limited or humid regions
335 (Fig. 6).

336 The temporal agreement between annual droughts was low during the historical period
337 between the different metrics, and also with low spatial agreement, suggesting that the global
338 spatial patterns of annual drought severity usually did not agree between drought metrics (Fig.
339 7). The spatial agreement of drought conditions tends to increase under future climate change,
340 in particular for some metrics (e.g. precipitation-AED and precipitation-Et, precipitation-AED

341 and Et-AED, precipitation-AED and soil moisture). Nevertheless, the spatial agreement
342 between droughts on the annual scale between climatic indices, runoff, and ecological
343 droughts was low in both the historical experiment and the projected scenario, indicating
344 spatial inconsistency in replicating annual droughts among the different drought metrics
345 obtained from ESMs.

346

347 **4. Discussion**

348 This study analysed long-term evolution of different drought metrics on a global scale using
349 CMIP6 models from 1850 to 2100. These metrics represent different climatic, hydrologic, and
350 ecological variables. Results were presented for the historical experiment (1850-2014) and
351 future projections (2015-2100) under a high-emission scenario (SSP5-8.5). While numerous
352 studies assessed drought severity for future climate using CMIP6 models (e.g. Cook *et al.*,
353 2020; Ukkolaet *et al.*, 2020; Papalexiouet *et al.*, 2021; Wanget *et al.*, 2021; Guoet *et al.*, 2022; Zhao and
354 Dai, 2022), our assessment employed a larger number of drought metrics, including climate-
355 based (precipitation, precipitation-AED, precipitation-Et, Et-AED), hydrological-based (soil
356 moisture and runoff) and plant physiology-based metrics (LAI and NPP). An evaluation of this
357 variety of different metrics is essential to assess different drought types (meteorological,
358 agricultural/ecological and hydrological) and to determine their consistency in terms of
359 projected drought severity. Our results, as suggested by most models and drought metrics,
360 suggest that drought would increase in southern North America, Central America, the Amazon
361 region, the Mediterranean, southern Africa, and southern Australia, which agrees with earlier
362 studies (e.g. Cook *et al.*, 2020; Ukkolaet *et al.*, 2020; Seneviratneet *et al.*, 2021; Wanget *et al.*, 2021;
363 Zhao and Dai, 2022). Also, in accordance with previous studies (Cook *et al.*, 2020; Scheff *et al.*,
364 2021), our results showed important differences in drought projections as a function of
365 drought metrics. For example, the use of AED-based drought metrics(e.g. the Standardised
366 Precipitation Evapotranspiration Index (SPEI)) revealed that drought severity is likely to

367 enhanced in future , as compared to those metrics based on precipitation, precipitation-Et,
368 and runoff. This finding agrees with some investigations based on CMIP6 (e.g. Zeng *et al.*,
369 2022), and CMIP5 outputs (e.g. Cook *et al.*, 2014) and also by studies that employed other
370 metrics like the Palmer Drought Severity Index (PDSI) (e.g. Scheff *et al.*, 2021; Yang *et al.*, 2021;
371 Zhao and Dai, 2022). The different magnitude of drought as simulated based on hydrological
372 (i.e. runoff) and climatic drought indices (which use AED in the calculations) is behind the
373 overestimation of drought severity based on climatic indices under high emissions climate
374 change scenarios as suggested by some studies(Berg and Sheffield, 2018; Scheff, 2018; Greve
375 *et al.*, 2019; Berg and McColl, 2021).

376 While it can be argued that focusing on the metrics directly indicative of impacts in
377 agricultural, ecological and hydrological systems (i.e. soil moisture, runoff, net primary
378 production, and leaf area index) instead of climatic proxies of drought severity can be a more
379 practical approach (McColl *et al.*, 2022), we believe that models can show uncertainties in
380 simulating complex hydrological and plant physiology processes. In addition, hydrological and
381 ecological outputs from CMIP models could be affected by more uncertainty in comparison to
382 climatic metrics that can be simulated easier, irrespective of any possible coupling
383 mechanisms. For example, the spatial and temporal variability in soil moisture involves several
384 processes, some of them are unknown, while others are difficult to simulate (van den Hurk *et*
385 *al.*, 2011; Lu *et al.*, 2019). This may explain poor agreement between soil moisture
386 observations and model simulations (Yuan and Quiring, 2017; Ford and Quiring, 2019).
387 Streamflow generation is also very complex and models usually fail to simulate hydrological
388 droughts (Tallaksen and Stahl, 2014; Barella-Ortiz and Quintana-Seguí, 2018). Plant physiology
389 is also a key factor controlling both hydrological, agricultural and ecological droughts, and
390 models show strong limitations and uncertainties in simulating plant physiological processes
391 and water interchanges with soil and atmosphere (Liu *et al.*, 2020). These problems are even
392 more important for future climate projections (Gentine *et al.*, 2019), given that other

393 processes may introduce other sources of uncertainty (e.g. the role of atmospheric CO₂
394 concentrations) (De Kauwe *et al.*, 2021). Therefore, although some studies argue that plant
395 and hydrological drought metrics obtained from model simulations can probably be more
396 accurate than AED-based climatic indices, we believe that these metrics may also be affected
397 by several strong uncertainties.

398 One of the novelties of our study is the use of diverse metrics, which is fundamental to address
399 drought characteristics and impacts. In particular, we employed the Standardised
400 Evapotranspiration Deficit Index (SEDI), based on the difference between Et and AED, which is
401 informative on plant water stress (Kim and Rhee, 2016; Vicente-Serrano *et al.*, 2018; Li *et al.*,
402 2019, 2020; Zhang *et al.*, 2019; Alsafadi *et al.*, 2022; Jiang *et al.*, 2022) with several
403 biogeographic implications (Stephenson, 1990). Changes in the SEDI, both in spatial patterns
404 and drought severity, were almost similar, or even stronger than those obtained by the SPEI,
405 and are characterised by an increase in drought severity under future scenarios of high
406 anthropogenic emissions. In addition, we used two eco-physiological metrics, LAI and NPP,
407 which have been considered by few studies as metrics of drought severity in model
408 simulations(e.g. Scheff *et al.*, 2021). As opposed to the SEDI, our assessment based on the LAI
409 and NPP did not suggest an increase in agricultural and ecological drought severity, except for
410 the high latitudes of the Northern Hemisphere. This may be explained by the role of snow and
411 permafrost melt processes that could affect water availability (Chen *et al.*, 2021).

412 The picture provided by our eight drought metrics showed some paradoxical projections that
413 are difficult to explain by coherent hydrological and plant physiological processes. In particular,
414 different studies focusing on plant physiology have highlighted that plant mortality will
415 strongly increase in future as a consequence of increased plant water stress and air
416 temperature (e.g. Williams *et al.*, 2013; McDowell and Allen, 2015; Xuet *et al.*, 2019; Brodribbet
417 *et al.*, 2020). This assessment is consistent with observations of ecological and agricultural
418 impacts of droughts, which are clearly reinforced by the observed increase in AED (Breshears

419 *et al.*, 2005, 2013; Allen *et al.*, 2010; Carnicer *et al.*, 2011; Lobell *et al.*, 2011; Asseng *et al.*,
420 2015; Sánchez-Salguero *et al.*, 2017). Nevertheless, in opposition to this empirical evidence
421 and the strong increase of drought severity as suggested by some climatic indices, LAI-based
422 drought projections suggested that –in few cases where precipitation is projected to
423 increase(e.g. Central America, southwestern Australia and the south of the Amazon region),
424 drought severity is likely to increase in future simulations.

425 The limited increase in drought severity based on ecological metrics is difficult to be supported
426 according to the widely known response of plants to water availability (Vicente-Serrano *et al.*,
427 2020b) and atmospheric water demand (Breshears *et al.*, 2013; Grossiord *et al.*, 2020),
428 particularly in water-limited regions where meteorological droughts (e.g. southern Africa,
429 southern North America, and the Mediterranean), and AED are projected to increase (Scheff
430 and Frierson, 2015; Vicente-Serrano *et al.*, 2020d). These conditions can lead to a remarkable
431 increase in plant water stress incompatible with increases in LAI and NPP. Thus, the only way
432 to avoid changes in ecological droughts in water-limited regions, where climate aridity is
433 projected to increase, is probably related to the physiological effects of the atmospheric CO₂
434 concentrations (Mankin *et al.*, 2017; Gonsamo *et al.*, 2021; Scheff *et al.*, 2022). Several studies
435 have showed a reduction in the leaf stomatal conductance and plant resistance to water stress
436 in response to enhanced atmospheric CO₂ concentrations (e.g., Ceulemans and Mousseau,
437 1994; Ainsworth and Long, 2005; Donohue *et al.*, 2013; Green *et al.*, 2020). However, the
438 effects of increasing CO₂concentrations on ecological and agricultural drought severity are very
439 complex (Allen *et al.*, 2015; De Kauwe *et al.*, 2021), and there are still several uncertainties in
440 the assessment of these effects based on ESMs (Gentine *et al.*, 2019; De Kauwe *et al.*, 2021),
441 tended to overestimate the effects of increasing CO₂ concentrations on plant physiology (Kolby
442 Smith *et al.*, 2015; Marchand *et al.*, 2020; Zhao *et al.*, 2020). Moreover, CO₂ effects would not
443 ameliorate plant stress during periods of water deficit, given that leaf stomatal conductance
444 would not be controlled by CO₂ concentrations, but mostly by soil moisture content (Morgan

445 *et al.*, 2004; Xu *et al.*, 2016; Menezes-Silva *et al.*, 2019). Therefore, our assessment of future
446 agricultural and ecological droughts based on model simulations is highly uncertain given the
447 current evidence of the responses of plants to enhanced water stress and AED and the several
448 sources of uncertainty in the modelling of the carbon cycle by the ESMs (Padrón *et al.*, 2022).
449 Thus, it is difficult to argue that ecological droughts will not increase in areas in which models
450 suggest a strong decrease in precipitation and a remarkable increase in AED.
451 For hydrological drought projections, our study indicates that future projections of droughts
452 quantified with soil moisture tend to resemble the pattern of the projections of drought
453 severity using SPEI. This seems to disagree with some previous studies that had suggested less
454 increase in soil moisture deficits than the decrease in meteorological indices including AED in
455 future drought projections (Milly and Dunne, 2016; Berg and Sheffield, 2018). This
456 disagreement can basically explained by the different statistical methods used to assess future
457 projections. These models are strongly affected by the autocorrelation of the drought metrics,
458 as well as by focusing on changes in the average values versus the tails of the complete set of
459 the distribution values (Vicente-Serrano *et al.*, 2020a). Thus, the last IPCC report has showed a
460 strong increase in drought severity worldwide based on extreme events of the total column
461 soil moisture, particularly during the boreal summer season (Seneviratne *et al.*, 2021). This
462 increase in the duration and magnitude of soil moisture deficits would be coherent with an
463 increase in agricultural and ecological drought severity, even more considering the strong
464 increase in AED, as projected by the CMIP models (Scheff and Frierson, 2015; Vicente-Serrano
465 *et al.*, 2020d), which would cause enhanced plant stress. Also, uncertainties in the projected Et
466 are noticeably affect drought projections based on precipitation-Et, which is usually considered
467 a metric of water availability. Thus, it is curious that the projections of meteorological droughts
468 based on precipitation showed a stronger increase in drought duration and magnitude than
469 projections based on precipitation-Et and runoff. It would be expected that hydrological
470 droughts will not increase at similar rates of agricultural and ecological droughts, in response

471 to increased AED. This is basically because the response of streamflow to enhanced AED is
472 expected to be lower than to precipitation, as observed with streamflow data (Ficklin *et al.*,
473 2018; Yang *et al.*, 2018; Vicente-Serrano *et al.*, 2019). This issue has been well-established
474 based on the ESMs, as runoff simulations mostly respond to precipitation at short time scales
475 (Scheff *et al.*, 2022). However, even responding more to precipitation than to AED, it is difficult
476 to support a smaller increase in drought severity by runoff than by precipitation under
477 scenarios of a high increase in AED. This behaviour would be mostly explained by the
478 suppression of Et as a consequence of the decreased leaf stomatal conductance given the
479 enhanced atmospheric CO₂concentrations, which would reduce the severity of hydrological
480 droughts (Roderick *et al.*, 2015b; Milly and Dunne, 2016; Yang *et al.*, 2019). However, a main
481 constrain of this assessment is that the influence of this mechanism on future Et is highly
482 uncertain in ESMs (Vicente-Serrano *et al.*, 2022a). Moreover, Et is also observed to increase
483 during dry periods (Zhao *et al.*, 2022) and evaporation in surface water bodies is expected to
484 increase in future scenarios (Wang *et al.*, 2018). For these reasons, it is difficult to argue that
485 hydrological droughts quantified using precipitation-Et and runoff will increase less than
486 meteorological droughts, based on precipitation, in future scenarios.

487 In addition to the comparative assessment of drought trends based on different drought
488 metrics, another aspect of novelty in our study is that it assesses the spatial and temporal
489 relationship between different drought metrics under the historical experiment and future
490 SSP5-8.5 scenario. Specifically, we found that the temporal relationship between the
491 precipitation-based climatic metrics (i.e. precipitation, precipitation-AED, and P-Et) is high
492 worldwide, with some spatial exceptions (e.g. in water-limited regions for P-Et). This behaviour
493 is expected given that precipitation is a main controller of the interannual variability of
494 drought conditions(Vicente-Serrano *et al.*, 2015; Tomas-Burguera *et al.*, 2020b). For example,
495 in the case of SPEI, precipitation explains more than 90% of the variability of this index, while
496 AED is only relevant during periods of precipitation deficit, particularly in water-limited regions

497 (Tomas-Burguera *et al.*, 2020b). This main role of precipitation is also observed in other
498 drought indices such as the PDSI (van der Schrier *et al.*, 2013; Vicente-Serrano *et al.*, 2015). On
499 the other hand, under the SSP5-8.5 scenario, the correlation between precipitation and AED-
500 based drought indices is expected to decrease, suggesting a greater role of AED. Nevertheless,
501 this temporal relationship remains high in most world regions.

502 The close relationship found between climate drought indices in historical and future
503 simulations contrasts with the low correlations found between climatic and ecological drought
504 indices, given the low percentage of years when drought conditions coincide following
505 meteorological and ecological metrics. The interannual variability of LAI and NPP showed high
506 agreement in both the historical period and in the future scenario. This is in agreement with
507 observations recorded in the last decades using vegetation activity from satellites (as a
508 surrogate of the leaf area) and tree-ring growth (as a surrogate of NPP) (Vicente-Serrano *et al.*,
509 2016, 2020c). Nevertheless, unexpectedly, we noted a poor relationship between the temporal
510 evolution of both LAI and NPP and the climatic drought indices, albeit with the use of a wide
511 set of metrics used here that highly represent plant water stress conditions (e.g. Et-AED).
512 Moreover, this low relationship is also found between the ecological variables and soil
513 moisture, which is one of the main factors controlling vegetation activity and carbon uptake
514 worldwide (Green *et al.*, 2019). This low relationship between climatic indices (and soil
515 moisture) and ecological metrics could be explained by the uncoupling between water
516 availability and plant water requirements as a consequence of the physiological effects of
517 atmospheric CO₂ concentrations (as discussed above). Nevertheless, low interannual
518 correlations were also found in the historical experiment. We consider that the low
519 relationship between ecological drought metrics and climatic and soil moisture metrics
520 introduces another important source of uncertainty in the assessment of the drought severity
521 under future climate scenarios. It is expected that the agreement between NPP, LAI, and the
522 different climatic metrics and soil moisture should be high, given the climate forcings used in

523 the historical experiment. Thus, based on different vegetation metrics, numerous studies
524 found strong temporal correlations between climate drought indices and soil moisture and
525 different ecological measurements in the past decades, including satellite metrics (e.g.
526 Vicente-Serrano *et al.*, 2013; Bachmair *et al.*, 2018), and tree ring growth (e.g. Orwig and
527 Abrams, 1997; Vicente-Serrano *et al.*, 2014). This unexpectedly low correlation between
528 climatic droughts, soil moisture deficits and agricultural and ecological droughts during the
529 historical experiment suggests that the temporal decoupling between these metrics is not
530 related to the possible physiological effects of the enhanced CO₂ concentrations. Rather, it can
531 probably be due to the existing limitations of the models in reproducing the real physiological
532 response of vegetation to drought. In addition to the low temporal concordance, there is a
533 general spatial disconnection between the occurrence of climatic and ecological droughts in
534 different regions worldwide.

535 The temporal agreement between climatic drought metrics, soil moisture, precipitation-Et, and
536 runoff is also low, both in the historical experiment and the SSP5-8.5 scenario. With the
537 exception of the tropical and subtropical regions in the case of runoff, the remaining world
538 showed low correlations with climatic metrics. Thus, the temporal correlations were low
539 between the interannual variability of soil moisture and runoff in most regions of the world.
540 This suggests that, considering climatic and hydrological drought metrics, the consistency of
541 ESMs simulations on long temporal scales (i.e. annual) may be also affected by uncertainties.
542 Thus, as opposed to CMIP6 outputs, the interannual variability of observed soil moisture and
543 streamflow is highly consistent with climate variables in most basins of the world (Dai, 2021).

544

545 **5. Conclusions**

546 This study provided new evidence on the interannual relationships and long-term trends
547 between drought types based on different drought metrics obtained from ESM simulations.
548 The main conclusion is that the coherence of the trends and the interannual relationships

549 between drought metrics show important uncertainties that can largely impact any robust
550 assessment of drought projections under scenarios of enhanced emissions of greenhouse
551 gases. Although some previous studies have suggested that the use of climatic drought indices
552 could overestimate drought severity under future scenarios, this study indicates that
553 projections based on hydrological (i.e. soil moisture and runoff) and ecological drought metrics
554 (i.e. NPP and LAI) can introduce uncertainties and inconsistencies, particularly for the
555 projected interannual relationship between drought metrics, as well as expected drought
556 impacts under scenarios of high emissions of greenhouse gases and strong temperature
557 increase. Still, there are several sources of uncertainty, particularly linked to the plant
558 processes and the physiological influences of the enhanced CO₂ atmospheric concentrations,
559 which have important implications for the assessment of both ecological and hydrological
560 droughts in future scenarios. Recent evidence highlights increased drought effects on crop
561 systems and natural environments in response to drought events characterised by warmer
562 conditions (Breshears *et al.*, 2013; Williams *et al.*, 2013; Fontes *et al.*, 2018), but also
563 hydrological implications given enhanced evaporation from crops, natural vegetation, and
564 water bodies (Vicente-Serrano *et al.*, 2017; Friedrich *et al.*, 2018; Althoff *et al.*, 2020). Although
565 the response of plant physiology and hydrological processes could change in the future, with
566 more adaptive strategies to much warmer conditions leading to a reduction in the severity of
567 hydrological, agricultural, and ecological droughts compared to climatic droughts conditions,
568 these scenarios may be uncertain. Therefore, the same (or even greater) criticism could be
569 made of the drought severity projections based on climatic drought indices using plant and
570 ecological metrics, as these metrics do not seem to respond coherently in time and space to
571 the occurrence of meteorological droughts and seem to underestimate the strong role of
572 warming processes, already evident in some hydrological systems, but mostly in agricultural
573 and ecological ones.

574 Drought severity projections are an extremely relevant topic with several environmental and
575 socioeconomic implications, which deserves some scientific debate. Nevertheless, several
576 studies based on models can present considerable uncertainties. Indeed, improving the
577 knowledge and modelling of the complex processes involved could reduce these uncertainties,
578 but we are probably still far from finding this solution. A focus on simple, but robust models, as
579 suggested by McColl *et al.*(2022), could be a better approach to improve the assessment of
580 future drought severity. However, this robust assessment may actually be simpler, as in future
581 periods of precipitation deficits (anthropogenic or naturally-induced), the projected increased
582 warming will cause more stress on hydrological and environmental systems as observed in
583 near-present climate, irrespective of the projected trends in precipitation.

584
