15   **Key words:** Northern Apennines, extensional tectonics, paleoseismology, capable faults, low

16   angle normal fault.

17   **Key points:**

18   ● Revealed the Late Pleistocene - Holocene slip history of the Anghiari fault, considered a

19   synthetic splay of a low-angle normal fault.

20   ● The capability of the Anghiari fault to rupture the surface during M>6 earthquakes has been

21   ascertained.

22   ● The results have potential implications for the activity and seismogenic behavior of a

23   continental low-angle normal faults.

24

25   **Abstract:** The NE-dipping Anghiari normal fault (AF), bounding to the west the Sansepolcro

26   basin in the Upper Tiber Valley (northern Apennines), is supposed to be a synthetic splay of the

Altotiberina (ATF) low-angle normal fault (LANF), an active ENE-dipping extensional detachment whose seismogenic behavior is debated.

In order to assess the AF capability to break the surface during strong earthquakes and be the source of historical earthquakes, we acquired high resolution topographic data, performed field survey and geophysical investigations (Seismic reflection, Ground Penetrating Radar (GPR), Electrical Resistivity Tomography (ERT)) and dug three paleoseismological trenches across different fault sections of the AF.

The acquired data reveal for the first time the Late Pleistocene to historical activity of the AF, constraining the age of seven paleo-earthquakes over the last 25 ka, the youngest of which is comparable with one of poorly constrained historical earthquakes of the Sansepolcro basin. The yielded slip rate is > 0.2 mm/yr averaged over the last 25 ka and the recurrence interval is about 2500-3200 years. The magnetic susceptibility analysis in one of the trenches indicates continuous extensional stress field across the entire trenched stratigraphy.

Our results confirm the ability of the AF to nucleate surface faulting earthquakes and suggest that the ATF (LANF) could have a seismogenic behavior, generating M>6 earthquakes, if the AF is soling at depth into the LANF.

Plain Language Summary: In this study we analyzed the capability of the Anghiari fault (Upper Tiber Valley, Northern Apennines of Italy) to reach and break the topographic surface during a strong earthquake. This fault belongs to the Altotiberina low-angle normal fault (ATF), a detachment fault accompanied by a system of synthetic splays whose seismogenic behavior is still debated because of a lack of seismological and paleoseismological data. Thanks to geological, morphotectonic and geophysical analyses, four sites have been selected for paleoseismological investigation. The paleoseismological data revealed the seismic history of the Anghiari fault, assessing its capability to recurrently break the surface during strong earthquakes.

In addition, an analysis of the anisotropy of the magnetic susceptibility performed in one of the paleoseismological trenches indicates that the stress field was extensional, acting continuously during the sedimentation of the entire trenched stratigraphy.

Our results suggest that the AF is capable to break the surface during strong earthquakes. This has potential implications on the seismogenic behavior of the ATF low-angle normal fault, as the strong earthquakes should nucleate on the low-angle fault plane if the AF is soling at depth into that detachment.

1. Introduction

The NE-dipping Anghiari normal fault (AF) is the northernmost part of the Anghiari-Città di Castello main fault which bounds the western flank of the Sansepolcro basin (Upper Tiber Valley, Northern Apennines of Italy).

The AF is featured by the greatest evidence of recent activity as it raises Early-Middle Pleistocene continental deposits in its foot-wall in correspondence of the Anghiari ridge (Fig. 1) The faults belonging to the Sansepolcro basin fault system are supposed to be synthetic and antithetic splays of the debated Altotiberina (ATF) low-angle normal fault (LANF) (Fig. 1), considered as a major engine of the extension in the Upper Tiber Valley (UTV) (Boncio et al., 2000; Chiaraluce et al., 2007; Delle Donne et al., 2007; Brozzetti et al., 2009; Pucci et al., 2014). The ATF is among one of the worldwide potentially active continental LANFs (Webber, 2018), deserving the developments of a Near Fault Observatory (NFO) long term research infrastructure (https://www.epos-eu.org/tcs/near-fault-observatories/about).

The complex seismotectonic context of the UTV is emphasized by Brozzetti et al. (2009) who highlighted the different behavior between the northern sector, corresponding to the Sansepolcro

basin, and the southern sector, corresponding to the area SSE of Città di Castello. The occurrence of strong (M>5.5) earthquakes in historical times suggests that it is possible to find geological evidence of either primary (i.e., tectonic surface ruptures) or secondary (i.e., shaking-induced features) evidence of past earthquakes (McCalpin, 2009). However, paleoseismologic studies aimed at discovering chronologically constrained field evidence of prehistoric strong surface rupturing earthquakes related to the Sansepolcro basin fault system are still missing. Only a few tectonic geomorphology and Quaternary geology studies (Cattuto et al., 1995; Sani et al., 2009; Pucci et al., 2014; Benvenuti et al., 2016;), locally implemented with near-surface geophysical investigations (Delle Donne et al., 2007), are available.

Since the morphotectonic expression of the Anghiari fault is pronounced, we focused on this latter, in order to investigate its capability to break the topographic surface during strong earthquakes. We performed detailed geological and geomorphological mapping of the Anghiari fault by means of traditional field work and digital topographic data, including high-resolution digital surface model (DSM) from satellite imagery and local very high-resolution LIDAR digital terrain model (DTM). Near-surface geophysical techniques including Seismic Reflection (SR), Ground Penetrating Radar (GPR) and Electrical Resistivity Tomography (ERT) were used to plan and accurately locate the sites for paleoseismological trenching and analysis.

In this paper we will show present evidence of the Anghiari fault activity, data on its discrete, recurrent surface faulting events, likely associated with large earthquakes. The implications for the activity and seismogenic behavior of a continental LANF are also discussed.

2. Geological and seismotectonic setting

2.1. Geological background

The Northern Apennines are a NE-verging fold-and-thrust belt resulting from the overlapping of different tectonic units during the Miocene. From west to east, the involved units are the ophiolite-

bearing Ligurian unit, the Tuscan unit, and the inner and outer Umbria units (Pialli et al., 1998; Brozzetti et al., 2009; Barchi, 2010). Since the Late Pliocene, the resulting compressional structures have been superimposed by an extensional phase driven by an eastward-propagating set of low-angle detachments dipping ENE, imaged by seismic reflection profiles (e.g., CROP 03, Pialli et al., 1998). The youngest and still active fault is the ATF, a ∼70 km-long structure dipping 15°–20° which bounds the western flank of the Quaternary UTV (Barchi, 2010). The ATF has accumulated up to 10 km of extension since the Pliocene (Mirabella et al., 2011; Caricchi et al., 2015). GPS data reveal 2-3 mm/yr of present-day extension rate across the entire extending Apennines (Serpelloni et al., 2005; Mantenuto, 2008; D'Agostino et al., 2009; Hreinsdóttir & Bennett, 2009; Bennett et al., 2012). This is similar to the long-term geologic slip rate of the ATF (2.7 mm/yr Mirabella et al., 2011). The most recent synthetic splays of the ATF appear to be segmented by step-over relay zones that separate three tectonically-controlled Quaternary basins, the northernmost of which is the Sansepolcro basin (Fig.1), characterized by a more intense Quaternary normal fault activity, in particular along the Anghiari fault (Pucci et al., 2014).
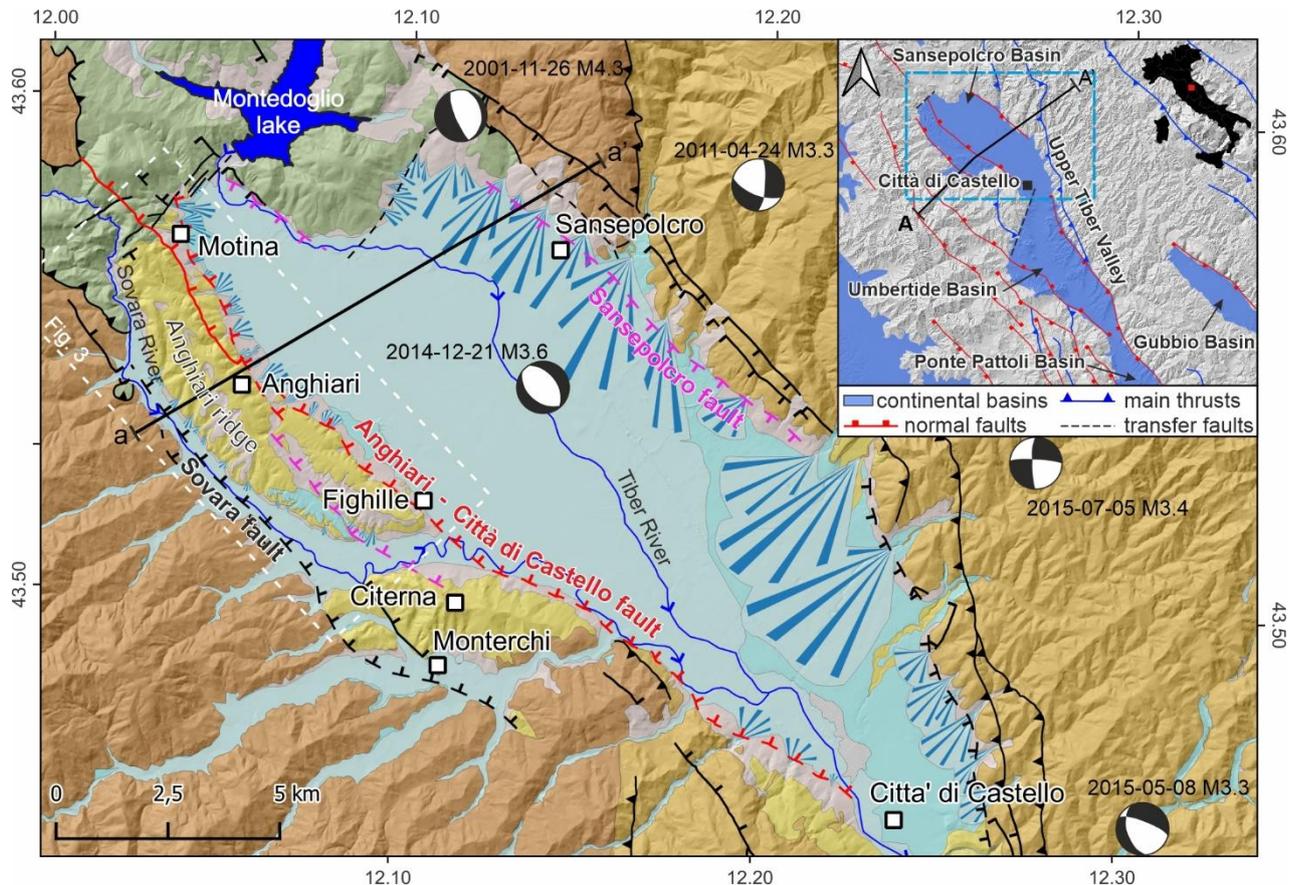

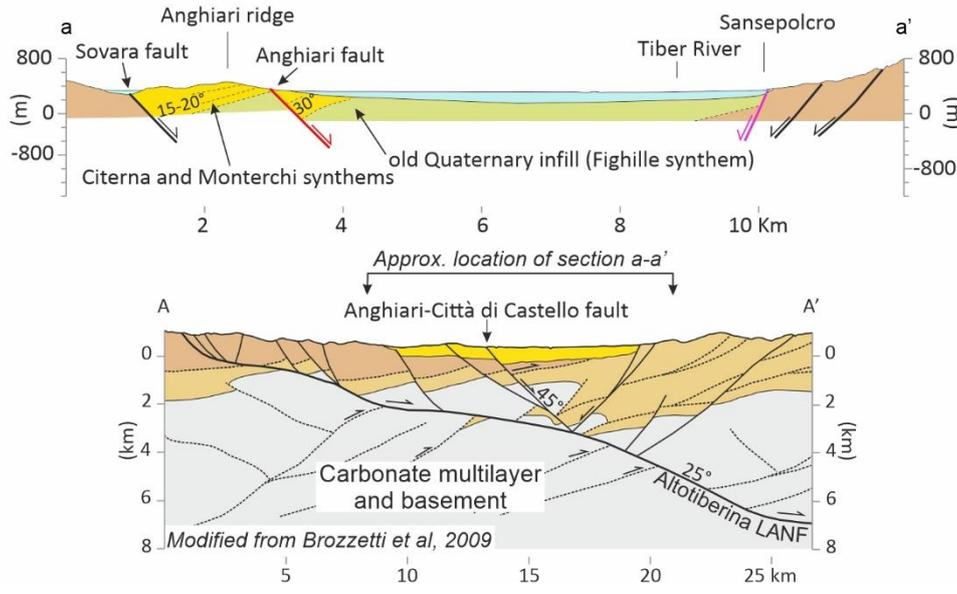

118   Fig. 1. Simplified geological map of the Sansepolcro basin showing the main tectonic units, the distribution of the

119   continental Pleistocene-Holocene deposits and the trace of the main faults. The faults affecting Upper Pleistocene-

120   Holocene deposits are defined as active faults, while the faults displacing Middle Pleistocene deposits or morphologies,

121   without more tightening age constraints, are defined as potentially active. The focal mechanisms are taken from RCMT

122   (available at http://rcmt2.bo.ingv.it/ last access Nov. 2022) and TDMT catalogs (available at

123   http://terremoti.ingv.it/tdmt last access Nov. 2022). The geological setting of the basin at shallow depth is shown in the

124   cross-section a-a'. The regional cross-section A-A', derives from the deep seismic line CROP3 (Barchi et al., 1998a),

125   modified from Brozzetti et al. (2009). The inset shows the location of both geological map and trace of section A-A',

126   along with the main tectonic features and basins of the Upper Tiber Valley.

127

128   The Sansepolcro basin is an asymmetric graben primarily controlled on the SW flank, by the

129 NE-dipping Anghiari-Città di Castello main fault and bounded, to the NE, by a SW-dipping antithetic

130 normal fault (Sansepolcro fault). This basin is infilled by a ~1.0-1.2 km-thick continental succession

131 (Barchi & Ciaccio, 2009; Mirabella et al, 2011; Pucci et al, 2014) (Fig. 1).

132   The Sansepolcro basin exposes mainly Holocene alluvial sediments within the valley, with

133 outcrops of Pleistocene deposits found mainly along its western side at the normal faults footwall

134 (Fig.1). The Quaternary continental deposits are made up of fluvio-lacustrine units, unconformable

135 covered by Middle Pleistocene to Holocene alluvial and colluvial deposits (ISPRA, 2011).

136   The Paleo Tiber River and its western and eastern tributaries fed the Sansepolcro basin with

137 a Quaternary deposition dominated by a fluvial-lacustrine/palustrine paleo-environment. Since the

138 Lower Pleistocene the opening of a wide extensional graben caused large infill of fine-grained

139 sediments in the depocenter and coarse sediments along its margins. In the Middle Pleistocene the

140 extensional activity started exhume the Anghiari ridge, with consequent interruption of the western

141 outflow and, determining the current basin physiography (Cattuto et al., 1995). Then, the drainage of

142 the basin has been affected also by the activity of the SW-NE striking faults that bound the basin to

143 the north, with consequent anomalies in the hydrographic network, such us fluvial deviations, of the

144 Tiber and Sovara Rivers (Cattuto et al., 1995; Benvenuti et al., 2016; Sani et al., 2009). After the

145   Middle Ages anthropogenic channeling shifted further east the Tiber River thalweg from the foot of

146   the Anghiari ridge (Cattuto et al., 1995).

147   There are no chronologic constraints for the sedimentary units infilling the basin, therefore

148   the unit ages and the stratigraphic frame is not univocal in the literature (e.g., ISPRA, 2011; Pucci et

149   al., 2014; Benvenuti et al., 2016). In this paper, we follow the basic stratigraphic frame defined in the

150   1:50,000-scale geologic map of Italy, consisting of three Pleistocene synthems (i.e., unconformity-

151   bounded stratigraphic units) (Fighille: FIG, Citerna: CTA and Monterchi: MTC) covered by Middle

152   Pleistocene to Holocene alluvial and colluvial deposits (ISPRA, 2011).

153   The oldest outcropping continental deposits belong to the Fighille synthem. It consists of

154   massive or planar-laminated clay and silt, with subordinate sandy and gravelly layers, deposited in a

155   fluvial-lacustrine/palustrine environment (i.e., periodically flooded alluvial plain, with ponds,

156   wetlands, rare braided streams, and alluvial fans) characterized by alternating dry and humid climate.

157   The clayey silts contain abundant plant remains, peats and lignite levels and calcareous nodules. The

158   Fighille synthem is at least 120 m-thick (the bottom never crops out) and is tilted westward (up to 25°

159   in the southern Anghiari ridge; Fig. 1). Its deposition started before 1.8 Ma, given the mollusk

160   assemblage and mammal faunas (late Villafranchian; Ciangherotti & Esu, 2000; Argenti, 2004;

161   Masini & Sala, 2007).

162   The Citerna synthem is characterized by coarse-grained facies association, with clast-

163   supported gravels in a sandy matrix, sand lenses and layers, clay lenses, and buried red paleosols of

164   a braided fluvial plain environment. In the footwall of the Anghiari fault, the Citerna beds are tilted

165   westward 15-20°, on average, while in the hanging wall of the fault the dip can be as high as ~30°

166   (see section a-a' in Fig. 1). The thickness of the unit is estimated in this work to be ≥ 150 m. Due to

167   the absence of radiometric dating, its age is inferred to be Early Pleistocene (Pucci et al., 2014) or

168   Middle Pleistocene (Benvenuti et al., 2016) only on the basis of stratigraphic relationships.

169   The Pleistocene fluvio-lacustrine sequence is closed upwards by the Anghiari sub-synthem

170   (member of the Monterchi synthem) which is made of reddish clayey silts, fine sands, and gravel

171   layers made of arenaceous, calcareous, and immature siliceous clasts. The thickness of the Anghiari

172   sub-synthem is estimated in this work to be in the order of 20-25 m, and the beds are tilted westward

173   5-10°. The top of this unit is highly weathered and presents stacks of paleosols with Mg-Fe-oxide

174   nodules and carbonate nodules, suggesting an alluvial environment affected by frequent subaerial

175   exposures during interglacial periods. Cattuto et al. (1995) suggested that the paleosol could be

176   formed during the Mindel-Riss interglacial, but a different age cannot be excluded, as there are no

177   chronological constraints for the age of the Anghiari sub-synthem and the overlying paleosols.

178   The Middle Pleistocene (upper part) to Late Pleistocene and Holocene alluvial deposits,

179   mostly made of gravels and sands, include terraced fluvial sediments of the Sovara and Tiber Rivers

180   and alluvial fans of variable thickness. Their age is constrained by morpho-stratigraphic relations

181   with the older units, by sparse radiocarbon dating and by archaeological constraints (Benvenuti et al.,

182   2016).

183   The deposition inside the Upper Tiber Valley has been influenced by the interaction between

184   regional uplift and tectonic subsidence. The geological and geomorphological evidence for

185   Quaternary activity along the UTV is concentrated within the Sansepolcro basin, where NE-dipping

186   splays reach the surface and bound to the west the Quaternary, fluvio-lacustrine deposits (Barchi et

187   al, 1998b; Boncio et al, 2000; Martini et al, 2001; Barchi e Ciaccio, 2009; Sani et al, 2009; Pucci et

188   al, 2014) (Fig. 1). In particular, the tectonic evidence consists of morphological fault scarps affecting

189   the Quaternary deposits, back-tilted Pleistocene alluvial terraces and syn-tectonic sedimentary

190   wedges that have been imaged by shallow high-resolution seismic profiles (Cattuto et al., 1995, Delle

191   Donne et al., 2007, Brozzetti et al., 2009). According to Pucci et al. (2014), the Sansepolcro basin

192   presents a lower vertical incision and elevated aggradation with respect to the southern basins,

193   suggesting that the subsidence rate, controlled by the Sansepolcro basin fault system, strongly

counteracts the regional uplift rate, as documented by the limited distribution of erosive forms such as fluvial terraces (see Fig. 1). The main NE-dipping faults are the Sovara fault and the Anghiari - Città di Castello main fault. The Sovara fault juxtaposes the pre-continental deposits bedrock to the Pleistocene continental units, bounding the western side of the basin, along the Sovara River valley (Fig. 1), and is presently buried under the Holocene alluvial deposits of the Sovara River. Present-day extension is accommodated by the Anghiari - Città di Castello main fault: it is a >20 km-long NE-dipping normal fault including two NW-SE aligned faults, the Anghiari fault to the north and the Città di Castello fault to the south, separated by the Sovara River Valley (Fig. 1) (Testa et al., 2021). The average throw-rate of the Anghiari fault was inferred to be ~0.25 mm/yr since the Middle Pleistocene, derived by the interpretation of a seismic reflection profile (Delle Donne et al., 2007), whilst 0.6-0.8 mm/yr was inferred for the Late Quaternary period based on the tilting of a fluvial terrace tread (Brozzetti et al., 2009). None of those numbers have been constrained by faulted dated markers (Fig. 1).

2.2. Seismicity and seismotectonic

Active extension across the Upper Tiber Valley is indicated by geodetic data (D'Agostino et al., 2009) and earthquake focal mechanisms (Pondrelli et al., 2002) (Fig. 1). The area of maximum extension is concentrated across a 30–40 km-wide zone where the strongest tectonic moment is released (D'Agostino et al., 2009). The correlation between the present extensional tectonics and the activity of the NE-dipping ATF is widely agreed in the literature (e.g., Barchi et al., 1998a; Boncio et al., 2000; Piccinini et al., 2003; Chiaraluce et al., 2007; Mirabella et al., 2011; Pucci et al., 2014; Anderlini et al., 2016; Gualandi et al., 2017; Valoroso et al., 2017). Based on the distribution and characteristics of the instrumental and historical seismicity, two sectors of the ATF were identified along the UTV and east of it: the northern sector, corresponding to the Sansepolcro basin studied in this paper, and the southern sector, SSE of Città di Castello.

219   The southern sector is characterized by diffuse, frequent microseismicity, located along the

220   zone around the ATF and within the ATF hanging wall, including doublets of repeating

221   microearthquakes, aseismic slip and small-magnitude slow-slip events (Piccinini et al., 2003,

222   Chiaraluce et al., 2007; Gualandi et al., 2017; Valoroso et al., 2017). Here, the most energetic

223   earthquakes are expected to be released by SW-dipping, NW-SE-striking antithetic normal faults

224   (e.g., the Gubbio normal fault, Mirabella et al., 2004; Pace et al., 2006) (Fig. 1). The northern sector,

225   i.e., the Sansepolcro basin, is characterized by much lower microseismicity activity, compared to its

226   southern counterpart, and was struck by several destructive historical earthquakes (Fig. 2). This has

227   been interpreted as the evidence that this segment is locked (Brozzetti et al., 2009), and supposedly

228   slipping during moderate to large earthquakes that nucleate at shallow depths on steeper ramps (25-

229   30°) of the ATF and/or on high-angle synthetic splays. In particular, the ATF ramp at 3-7 km-depth

230   and its continuation up to the surface along the Anghiari fault (see section A-A' in Fig. 1) has been

231   considered as the major potential seismogenic source of the area (named Città di Castello in Brozzetti

232   et al., 2009).

233   Dense network of GPS data, yield ~2-2.5 mm/yr of extension driven by the ATF, mostly

234   accommodated with creep below depths of 4-5 km (H Hreinsdóttir and Bennett, 2009; Anderlini et

235   al., 2016 The modeled geodetic strain (Anderlini et al., 2016) suggest that the ATF is mainly locked

236   down to 4-5 km of depth, whereas creeps at a rate of 1.7±0.3 mm/yr between 4-5 and 7 km, with a

237   deep locked patch between 7 and 10 km. According to Anderlini et al. (2016), one of the main shallow

238   locked patches is in the Sansepolcro basin. The main creeping portion correlates well with the area

239   of intense microseismicity SSE of Città di Castello. Such a fault architecture and slip behavior

240   produce a positive stress build up on the shallow locked portion of the ATF, and on most of the

241   hanging wall splays, including the Anghiari fault. Based on the size and Strain rate of the inferred

242   locked patches, Anderlini et al, (2016) estimated a seismic potential of the ATF up to Mw 6.5-6.7

243 over a time interval of 10^3 years. On the other hand, seismic slip on hanging wall splays might favor

244 potential seismic slip or transient acceleration of creep on deeper portions of the ATF.

245 Figure 2 shows the epicentral macroseismic intensities of the earthquakes that hit the Sansepolcro

246 basin in the past centuries. The main events ($M_w \geq 5.5$) are the 1352 (M_w 6.3, Mercalli-Cancani-

247 Sieberg macroseismic intensity - I_0 - IX-X), 1389 (M_w 6.0, I_0 IX), 1458 (M_w 5.8, I_0 VIII-IX), 1789

248 (M_w 5.8, I_0 X), 1917 (M_w 6.0, I_0 IX-X) earthquakes (Rovida et al, 2022). Other significant events

249 ($5 \leq M_w \geq 5.5$) are the 1489 (M_w 5.1, I_0 VII), 1558 (M_w 5.1, I_0 VII) and 1919 (M_w 5.0, I_0 VI) earthquakes

250 (Rovida et al, 2022). Based on the distribution of the intensity data points, Brozzetti et al. (2009)

251 proposed that the 1389, 1458 and 1789 could have nucleated on the southern sector of the Anghiari-

252 Città di Castello main fault, while the 1917 Monterchi earthquake could have nucleated on a western

253 and shallower synthetic splay of the ATF. Similarly, as possible evidence of NE-dipping source of

254 the 1917 earthquake, Delle Donne et al. (2007) consider as primary surface faulting the ~1 km-long,

255 NW-SE-striking coseismic ground failure occurred near Monterchi and described by Oddone (1918)

256 (although the latter did not exclude its landslide genesis). A different interpretation of the 1917

257 earthquake is proposed by Caciagli et al. (2019), who reanalyzed instrumental historical data and

258 calculated a relatively deep hypocentral location (~8±4 km-depth), a relatively high magnitude (Mw

259 5.8) and a first-arrival focal solution. The most plausible solution proposed by these authors is a NE-

260 striking right-lateral strike-slip fault in the footwall of the ATF, possibly related to a transfer fault

261 responsible for the segmentation of the ATF.

262 None of the seismotectonic interpretations mentioned above is constrained by paleoseismological

263 evidence in historical or Holocene layers that might prove the activity of the fault(s) up to the surface.

264   In this paper we present constraints on the Late Pleistocene and Holocene activity of the Anghiari
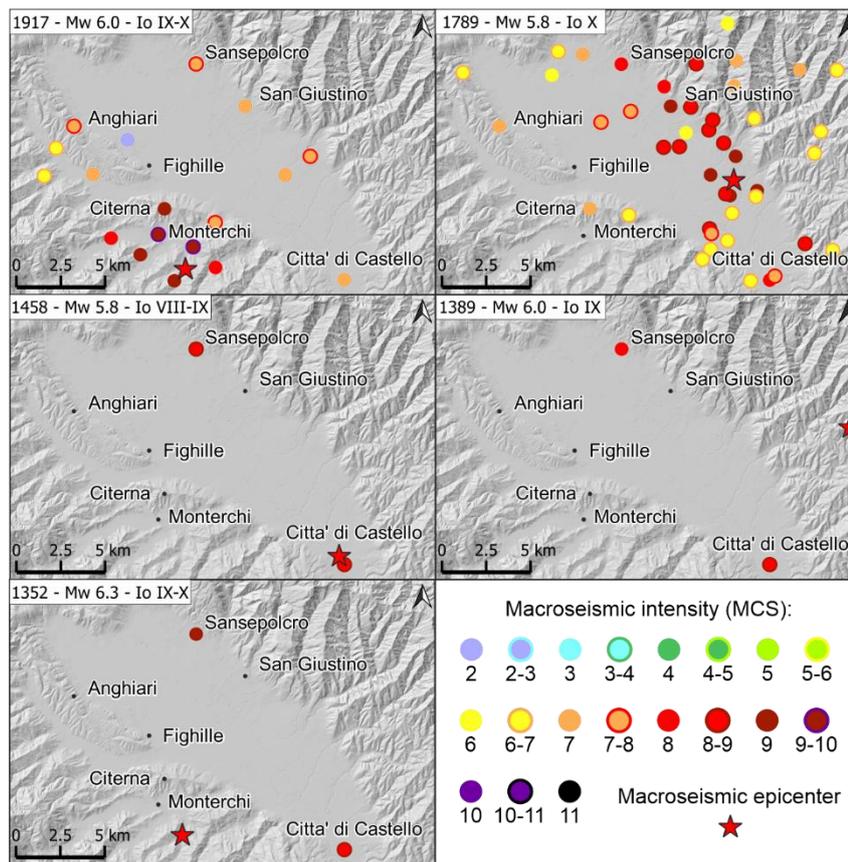

265   fault.

266   Fig. 2. Distribution of the macroseismic intensities related to the main historical earthquakes

267   ($M_w \geq 5.5$)occurred in the Sansepolcro basin. In detail the following events are represented in order: 1917 (M_w

268   6.0, Mercalli Cancani Sieberg macroseismic intensity I_0 IX-X); 1789 (M_w 5.8, I_0 X); 1458 (M_w 5.8, I_0 VIII-IX);

269   1389 (M_w 6.0, I_0 IX); h) 1352 (M_w 6.3, I_0 IX-X) (Rovida et al, 2022).

270

271   ## 3. Methods

272   ### 3.1. Field and remote sensing surveys

273   Field investigations and geological and geomorphological mapping were carried out along the

274   eastern side of the Anghiari ridge in order to map the surface trace of the Anghiari fault as well as to

275   identify faulted stratigraphic and topographic markers constraining the fault slip history and slip rate.

276   Most of the geologic and geomorphic features such as fault traces and the contacts of Quaternary

277   geological bodies were identified integrating both conventional field mapping and remote sensing

13

techniques: the former was performed using a field tablet integrating a commercial GPS device and a dedicated digital mapping suite (Field Move Software Suite, Petroleum Experts); the latter included the acquisition and analysis of LiDAR data, airborne-acquired through a Riegl miniVUX Sys DL laser scanner mounted on a DJI Matrice 600 pro drone. This acquisition produced a dense point cloud (300 pts/m^2) from which a very high-resolution Digital Terrain Model (DTM) (0.2-m pixel size) of 1.45 km^{2}was built. Then, the derivatives shaded relief, slope and aspect maps, were jointly and carefully analyzed (Figure 4). Moreover, at the scale of the Sansepolcro basin we used the 10 m resolution TINITALY Digital Elevation Model (DEM) (Tarquini et al., 2012) and a newly acquired Digital Surface Model (DSM) derived from stereo pairs of Pleiades satellite optical images (50 cm resolution).

3.2. Geophysical investigations (GPR, Seismic, ERT)

Following the field and geomorphological mapping, we carried out a geophysical campaign aimed at determining the most accurate position of the fault traces which could be the target for paleoseismological trenching. Across some site with morphological fault expressions, we have used/combined high-resolution seismic reflection (SR), ground-penetrating radar (GPR) and electrical resistivity tomography (ERT) acquisitions. Among the acquired datasets, here we present only the results achieved combining high-resolution SR and GPR at the Villa Sterpeto site (location in Fig. 3 and 4) and the ERT at the Anghiari site A (location in Fig. 4), surveyed at the paleoseismological investigation area and at the paleoseismological trench floor.

The SR profile was 167 m-long, ~58°N oriented, and acquired across the scarp between the slope made of Citerna synthem and the paleo-surface curved on the Anghiari sub-synthem.

A 24-bit DoReMi seismograph, manufactured by SARA Electronic Instruments (https://www.sara.pg.it) and equipped with 72 channels linked to vertical geophones (40 Hz), was

used for the acquisition of P-waves. The geophone spacing was set up to 1 m and thus 0.5 m was the CDP spacing. To increase the resolution along the near surface portion of the seismic section, a GPR profile 62 m-long and ~67°N oriented was collected crossing the possible fault trace, aiming to better constrain the fault geometry at shallow depth. The GPR line was recorded using a Zond-12e GPR system, equipped with a 100 MHz antenna (Tx and Rx), using a survey wheel and Topcon GR-5 GNSS device in NRTK configuration, to record the coordinates and elevation of each trace. Despite the clear high conductivity of the soil at the study site, limiting the probing depth to ~2 m, the processed GPR profile shows an improved image of the shallow geometries. The processed SEG-Y files were finally imported in the seismic interpretation software OpendTect Pro v.6.4 (academic license courtesy of dGB Earth Science, https://www.dgbes.com, last access: 3 January 2023) for an enhanced display obtained by the calculation of selected seismic attributes (Taner, 1979) computed on the GPR signal amplitude and phase, already proven to be effective detecting fractures and faults (Forte et al., 2012; Ercoli et. al., 2015). In particular, the instantaneous phase (Cinti et. al., 2015) enhances the interpretability of the reflections' geometry and the enhancement of lateral discontinuity. Being independent on the reflection strength, this attribute is also effective in strongly attenuated areas characterized by weak reflectivity (Ercoli et al., 2021a), thus propaedeutic for ground truthing. The latter aids not only the stratigraphic interpretation but also enhances lateral geophysical discontinuities associable to shallow fracturing and/or faulting.

A MAE XM612EM+ equipment has been used to acquire an ERT profile along the floor of the trench Anghiari site A, with a maximum electric voltage of 200V and a minimum electricity of 150 mA. The resulting resistivity profile has a maximum depth of 7-8 m and a spatial resolution of 0.5.

Further details about the acquisition and processing of the geophysical analysis are given in the supporting information (Text S1).

3.3. Paleoseismological trenching

The paleoseismological investigations were conducted between winter 2021 and summer 2022 in two sites across the Micciano fault section (Villa Sterpeto, Podere Todari sites) and two sites across the supposed trace of the Anghiari-Motina fault section (Anghiari sites A and B) (Figure 4). First we dug by backhoe a semi-benched trench, 60°-trending, 50 m-long and 3 m-deep at the Villa Sterpeto site, across the fault trace highlighted by the high-resolution SR and GPR data interpretation.

At the Podere Todari site, we widened and rectified by backhoe a pre-existing, 80°-trending anthropogenic roadcut exposing faulted colluvial deposits across a synthetic splay of the Micciano fault section. The wall of the rectified roadcut was 7 m-long and 2.5 m-high.

Finally, we dug two trenches by backhoe at the Anghiari sites A and B across the supposed trace of the Anghiari-Motina fault section. The trench of site A was 50°-trending, 55 m-long, 3 to 4 m-deep, with a benched layout. The trench of site B was 60°-trending, 40 m-long, 3 m-deep, with a benched layout. The location of the trench Anghiari Site A was chosen based on an outcrop of the Citerna synthem at the base of the scarp below the road S.P. 47 suggesting that the scarp is in the footwall of the fault and that the fault is located a few meters downslope. The location of the trench Anghiari site B would have to cross the supposed trace of the Anghiari-Motina fault section in order to compensate for the lack of unequivocal evidence in the site A. However, this trench is completely located within the hanging wall of the fault.

In all the four sites, the trench walls were accurately smoothed and cleaned. The faults and the main stratigraphic contacts were identified, flagged with colored pins, and logged. Wall logs were drawn at 1:50 scale for Villa Sterpeto and Anghiari sites and 1:20 scale for Podere Todari site. As a basis for the wall logs, four orthophotomosaics were generated from ground-based 24-megapixel imagery, acquired using a Canon 850d camera, and processed by structure-from-motion photogrammetry through Agisoft Metashape®. High-resolution orthophotomosaics are reported in supporting information (Figures S1, S2, S3 and S4).

In order to constrain the age of the earthquakes we performed a Bayesian analysis in OxCal v4.4.4 (Bronk Ramsey, 1995 and 2009; atmospheric calibration model by Reimer et al., 2020) using the Boundary-Zero Boundary model (Bronk Ramsey, 2008). This approach allowed us to compute the probability density function for the ages of the events, forcing the model to skew the age based on geological evidence interpreted as developed immediately before (i.e., earthquake horizons) or immediately after (colluvial wedges) the earthquakes. Therefore, the earthquake ages computed using OxCal are narrower than the time windows between each couple of samples, and the probability density function has a skewness through the sample that, according to our interpretation, fits much better with the age of the events.

3.4. Sample dating

We collected 18 samples from paleoseismological trenches for radiocarbon dating, 8 at the Villa Sterpeto, 6 at the Todari, and 4 at the Anghiari A sites. Charcoal was found and dated in 3 samples (Anghiari site A), the other samples consist of organic sediment, for which we dated the bulk organic fraction. The radiocarbon dating was performed with accelerator mass spectrometry technique in the laboratories of Beta Analytic for 13 samples (https://www.radiocarbon.com/, last access: 26 August 2022) and in the Laboratory Plateforme Nationale LMC14, France (http://lmc14.lsce.ipsl.fr/, last access: 21 March 2022), for 5 samples (complete list of the samples and samples age in Tab. 1). The uncalibrated ages given from the LMC14 laboratory were calibrated by us using the IntCal20 atmospheric calibration model (Reimer et al., 2020) in OxCal. The original reports of the dating, and the results of the calibration (referring to the samples dated in the Laboratory Plateforme Nationale LMC14) are reported in the additional supporting information. The age of six pottery shards collected in the Anghiari site A trench was estimated by O. Menozzi, archeological expert of the University of Chieti - Pescara (personal communication).

3.5. Anisotropy of magnetic susceptibility

The anisotropy of magnetic susceptibility (AMS) can be used as a proxy for rock fabrics (Hrouda, 1982; Borradaile, 1988; Tarling & Hrouda, 1993; Borradaile & Henry, 1997; Borradaile & Jackson, 2004), reflecting the preferred orientation of grains, grain distributions and/or the crystal lattices of minerals that contribute to the magnetic susceptibility of a rock (e.g., Tarling & Hrouda, 1993; Borradaile & Jackson, 2004).

In particular, AMS is extremely sensitive to incipient strain in fine-grained sediments well before other macro and mesoscopic strain features (such as cleavage) can be observed in the field. In general, in compressive tectonic settings, the magnetic lineation (the maximum susceptibility axis) is commonly parallel to fold axes and thrust faults, while in extensional regimes, it is perpendicular to normal faults and parallel to bedding dip directions (e.g., Borradaile & Jackson, 2004; Maffione et al., 2012).

In order to understand the relations between these units and the fault activity, the anisotropy of the magnetic susceptibility (AMS) of clay layers, the paleosol and the colluvial deposits was investigated in the Villa Sterpeto trench. Eight blocks were collected using a Bosch Professional 18V System GOP multitool. Each block was oriented with a Brunton magnetic compass and extracted, numbered from 1 to 8, where the latter is the closest to the fault in the Villa Sterpeto trench. Blocks ANG01 to 05 were collected in clays, ANG06 and 07 on the paleosol and ANG08 on the colluvial deposits. From each block, 5 to 8 oriented ~1.5 cm^3 cubes were cut using a diamagnetic saw, in the rock preparation laboratory at INGV, Rome. For each of the 50 samples, the bulk susceptibility and the low field AMS was measured on all samples on a AGICO KLY-3S Kappabridge and the results were processed using the AGICO software Anisoft (https://www.agico.com/text/software/anisoft/anisoft.php). Further information about this methodology is given in Supporting Information (Text S2)

4. Results

4.1. Anghiari fault from geological and geomorphological mapping
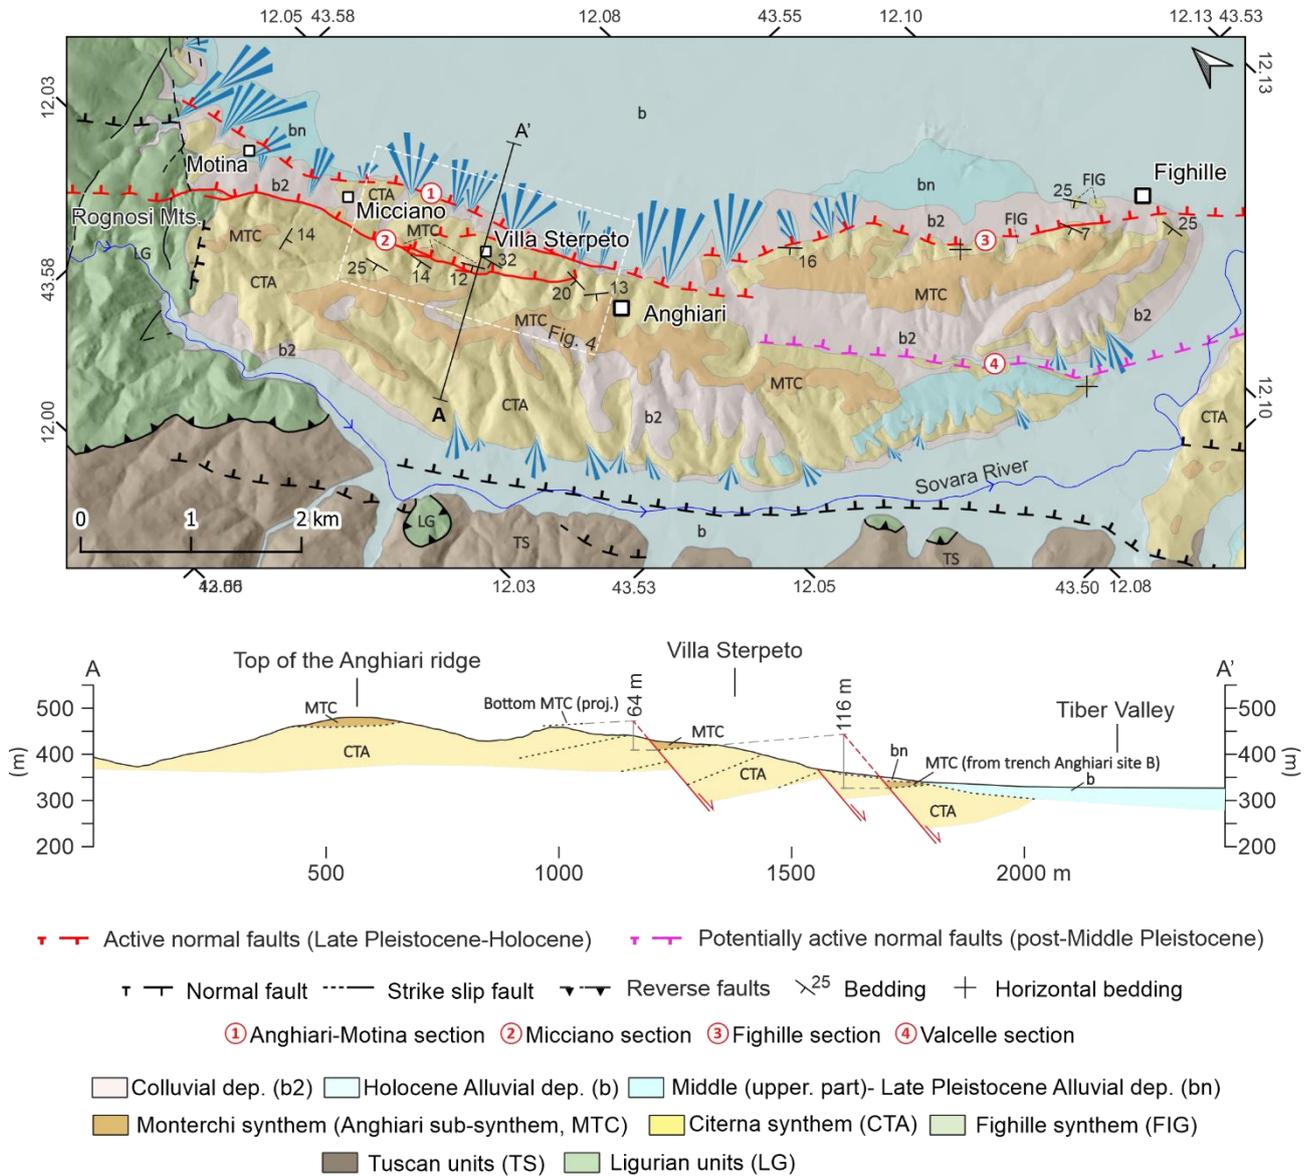

Fig. 3. Detailed geological map of the Anghiari ridge showing the distribution of the main geologic units and the segmentation of the Anghiari fault, based on ISPRA (2011) and integrated with original field survey. The measured displacement of each segment of the Anghiari fault is shown in the geologic cross section A-A' (no vertical exaggeration). Dashed lines indicate buried or inferred fault traces. See the caption of Fig. 1 for the definition of active and potentially active faults. The white dashed square indicates the location of the map in figure 4.

409   The Anghiari normal fault is characterized by a segmented pattern in map view, formed by at

410   least four fault sections, namely the Anghiari-Motina, Micciano, Fighille and Valcelle sections (1,2,3

411   and 4, respectively, in Fig. 3).

412   The 5.5 km-long Anghiari-Motina section bounds the eastern side of the Anghiari ridge,

413   separating the Citerna synthem (CTA) in the footwall from the Holocene colluvial and alluvial

414   deposits in the hanging wall. The fault trace is barely visible in the field and is often concealed by

415   anthropogenic modifications. Its trace was mapped using first-order morphological evidence, such as

416   escarpments on the CTA sediments uplifted in its footwall block, and the alignment of apexes of the

417   youngest generation of alluvial fans developing in its hanging wall. The fault location is further

418   constrained by data acquired within trenches A and B near Anghiari. The average strike of the

419   Anghiari-Motina section is N150. A 1.5 km-long, WNW-striking secondary splay (Fig. 4), crossed

420   by the geologic section in Fig. 3, branches out from the principal fault trace and displaces some

421   paleosurfaces located between the Anghiari-Motina and Micciano fault sections.

422   The 6 km-long Micciano section runs within the Anghiari ridge, from the Rognosi Mts. to the

423   northern part of the Anghiari town. In its northern sector, the fault separates the Meso-Cenozoic

424   bedrock (Ligurian units) from the Lower-Middle Pleistocene CTA unit and then continues to the NW

425   within the bedrock. The fault is characterized by prominent morphotectonic evidence, such as

426   triangular facets, deeply incised gullies, and down thrown paleosurfaces (See Fig. 4 for details). The

427   average strike of the Micciano section is N145.

428   The 4.8 km-long Fighille section runs at the base of the Anghiari ridge, from the southern part

429   of the Anghiari town to the Sovara River valley. A left step-over separates this section from the

430   Anghiari-Motina section. As first-order geomorphic evidence, the fault separates the Lower-Middle

431   Pleistocene CTA sediments of the Anghiari ridge from the Tiber River alluvial plain. At a closer

432   view, the fault trace is often concealed by anthropogenic modifications and its trace can be inferred

433 thanks to aligned escarpments on the CTA sediments and the alignment of the youngest generation

434 of alluvial fans in the hanging wall. The average strike of the Fighille fault section is N130.

435   The 5 km-long Valcelle fault section is located within a NW-SE-oriented valley that crosses

436 the Anghiari ridge, from the Anghiari town to the southern side of the Sovara River valley. It is

437 confined within the CTA synthem, without prominent geomorphic expression, except for the southern

438 part, where the fault crosses the Sovara River and forms a straight scarp within the CTA synthem, on

439 the southern side of the valley (Fig. 1). The average strike of the Valcelle fault section is N130. This

440 fault section is imaged as potentially active in Fig. 3 since it only affects Early-Middle Pleistocene

441 deposits.

442   The geologic section A-A' in Fig. 3 crosses orthogonally both the Micciano and Anghiari-

443 Motina fault sections, showing a throw component of 64-116 m of the MTC bottom, respectively
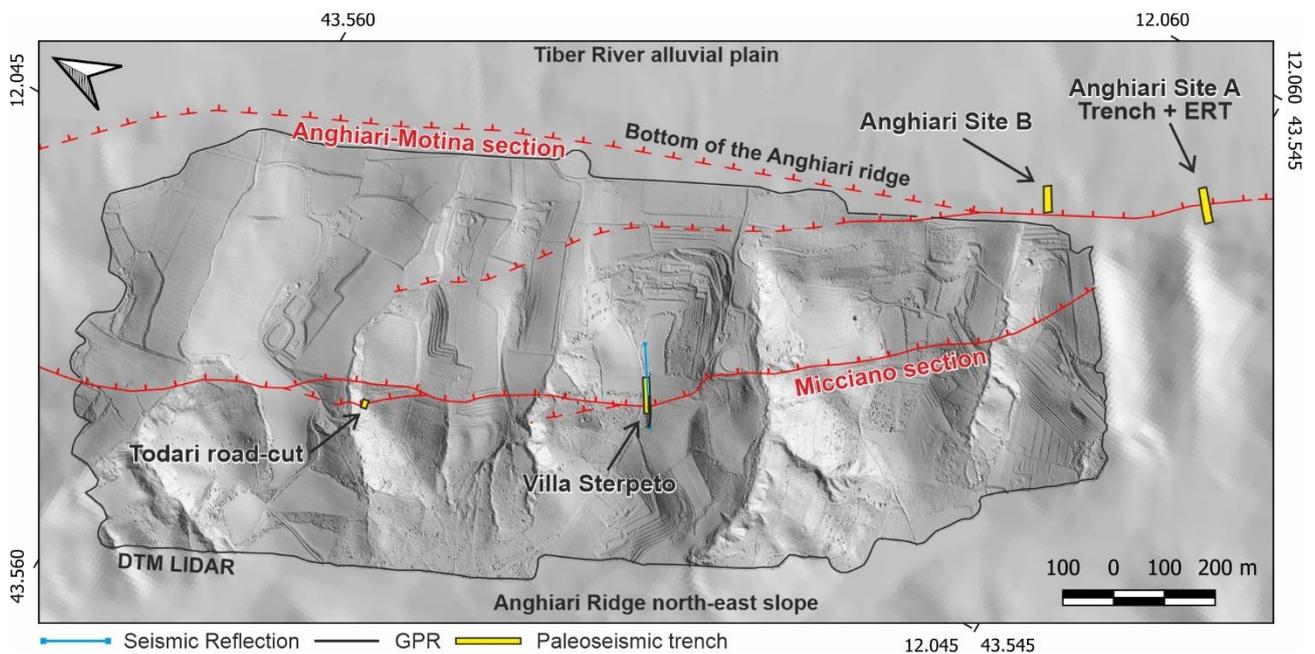

445   Fig. 4. Location map of the geophysical investigations and Paleoseismological trenches. The topographic maps

446 are the 10 m/pixel DTM TINITALY (Tarquini et al., 2012) and the newly acquired, 0.2 m/pixel DTM LIDAR. The traces

447 of the Anghiari-Motina and Micciano fault sections are shown in red.

4.2. Villa Sterpeto site

The following paragraphs illustrate the results of both geophysical and paleoseismological investigations conducted at Villa Sterpeto

4.2.1. Geophysics

The seismic reflection profile reveals two high amplitude, low frequency reflections, due to a strong acoustic impedance contrast, gently dipping toward east and located between 15 and 35 m of depth (Fig. 5a). Given the general WSW dip of the bedding in the area, we consider the dip of these reflections as apparent due to the seismic line strike and lack of depth migration. At distance 60 m, these two reflections are interrupted and displaced at depths of 15-20 m. This offset is interpreted as due to a NE-dipping normal fault. The projection at the surface of the interpreted fault (red line in Fig. 5a) intercepts the topography at distance between 45 and 60 m. However, the seismic line has a low reflectivity within the first ~ 10 m depth interval, insufficient to provide more details and insights on the stratigraphy and potential fault offsets. Another reflection discontinuity is visible between the distances 104-116 m (Fig. 5a), although the poorly coherent reflections, and the lack of displacement, do not constrain a reliable fault image.
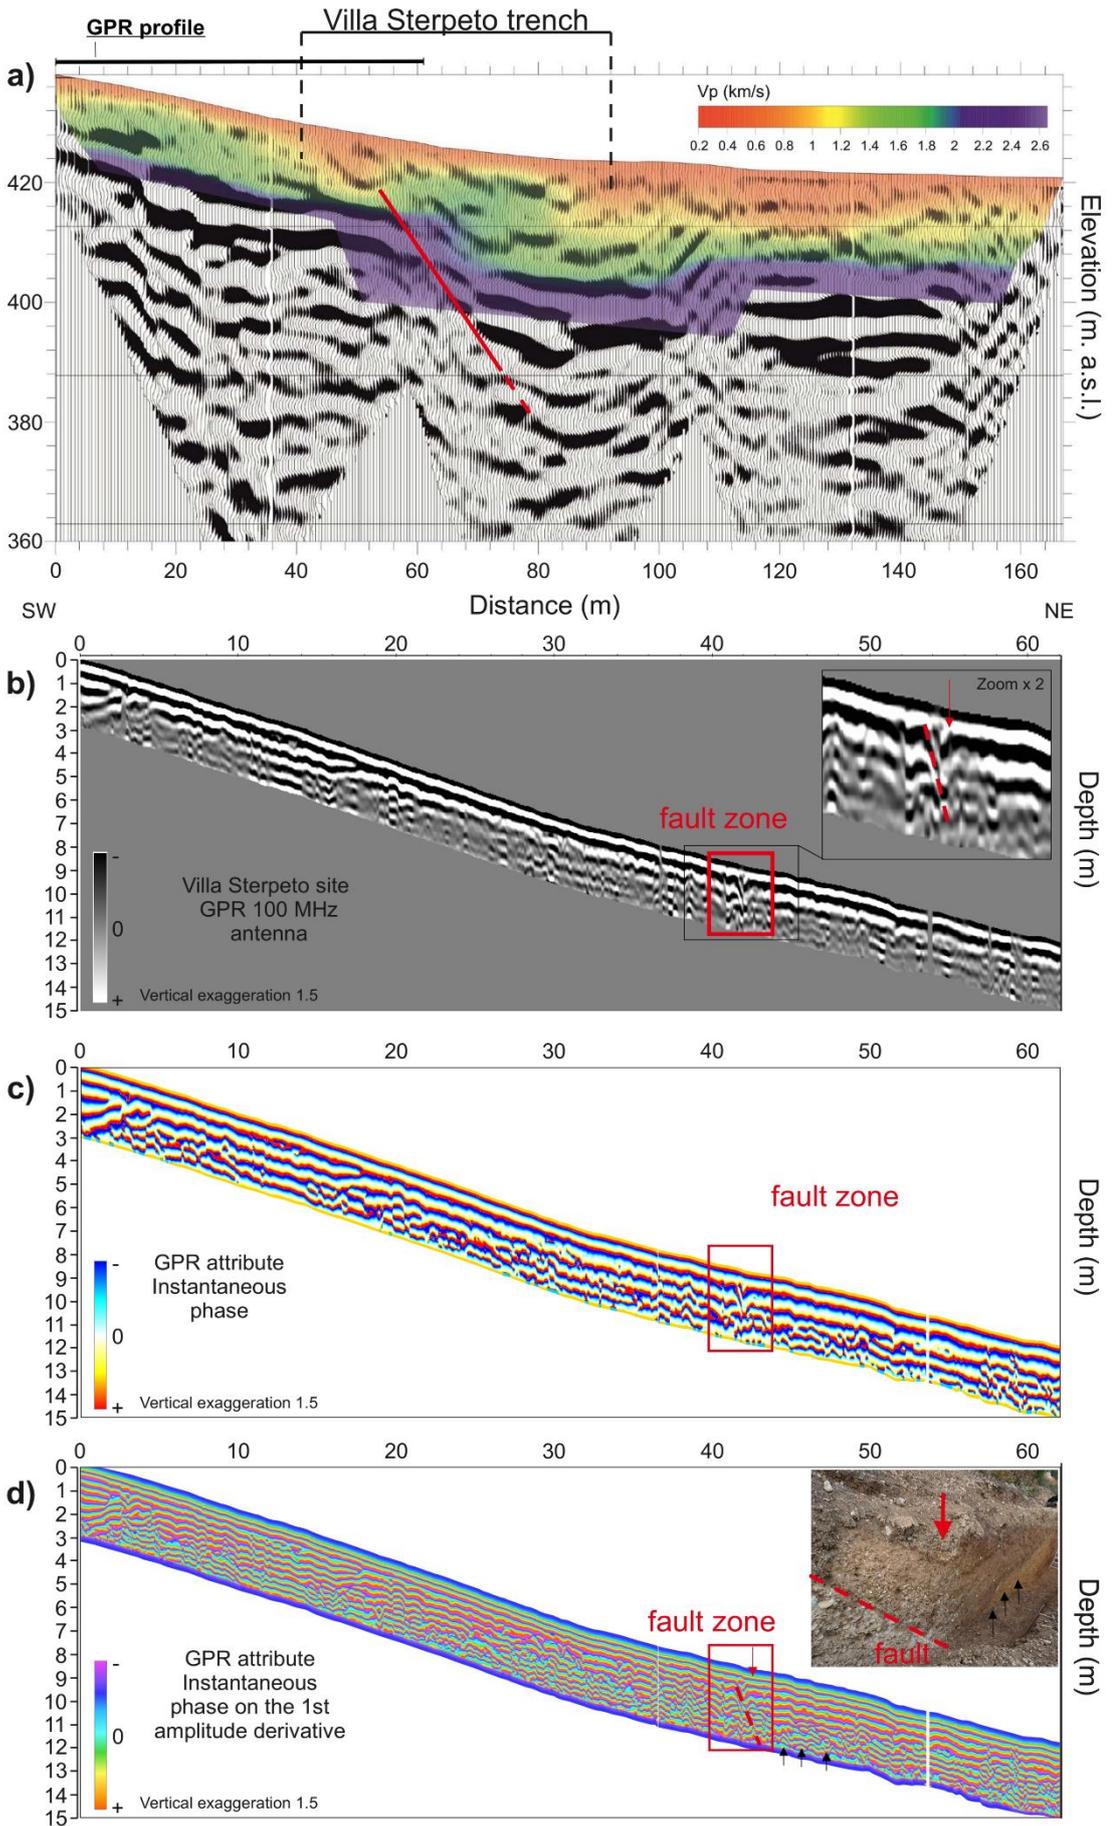

Figure 5: Geophysical data interpretation at the Villa Sterpeto site. a) Seismic reflection profile overlapped by

465 refraction tomography model (details in supporting information, Text S1), and by the interpreted normal fault (red line);

466 b) GPR profile; the red box points out the lateral radar discontinuity interpreted as a possible fault zone. c) instantaneous

467 phase attribute enhancing the continuity of reflections as well as the fault zone; d) the GPR attributes enhances the

468 geometries of the subsurface stratigraphy also in deeper sectors (3 m depth) characterized by low GPR reflection

469 amplitudes caused by high-attenuation, as well as across the fault zone; the GPR attributes aid the interpretation due to

470 higher level of details in comparison to b).

471

472 The GPR profile images the near surface portion of the transect, and it is characterized

473 by continuous shallow reflections in the first two meters. At depth down to 3 m, the strong attenuation

474 caused by the moderate to high conductivity of the deposits (ERT data available on the area show

475 resistivity generally <50 Ωm in the shallow subsurface) does not allow to clearly interpret the

476 stratigraphy. Analyzing more carefully the geometry of the shallower reflections, these show SW-

477 dipping reflections at distances 0-5 m and 16-18 m, which could represent the conglomerates mapped

478 in the footwall. A clear subvertical (E-dipping) discontinuity of GPR signal at ~ 42 m along the

479 profile, could be compatible with a fault, being a GPR signature including reflection truncation, dip

480 change and diffraction hyperbola (e.g., Ercoli et al., 2013, 2021b). This GPR signature appears as the

481 surface projection of the fault zone seen on the seismic line (Fig. 5a). This GPR discontinuity was

482 thus inferred as a possible fault zone, and it was later confirmed by ground trenching. Notice that the

483 GPR attributes displayed in Figs. 5c and 5d offer a higher degree of detail in comparison to the

484 conventional GPR profile of Fig. 5b. This consideration is confirmed not only by the enhancement of

485 the phase discontinuity across the fault (red dashed line), but also by the emphasized gentle inflection

486 of the shallower (hanging wall) deposits close to the fault, possibly including colluvial wedges (red

487 arrow). In addition, the stratigraphic mapping of the deposits geometry is also strongly improved not

488 only along the entire GPR profile, but also down to 3 m depth, where the attenuation, possibly due to

489 conductive clayey layers, reduced the reflections amplitude in Fig. 5b. This fact is particularly visible

490   within the basal contact between the gently W-dipping reflections (black arrows in Fig. 5d) and the

491   overlying layers. The latter profile demonstrates the capability of GPR attributes to recover

492   information which are hardly visible in conventional GPR profiles, increasing the data interpretability

493   also in relatively unfavorable conditions caused by conductive materials.

498   Tab. 1. Summary of radiocarbon dating analysis.

4.2.2. Stratigraphy and primary tectonic features

500   The Villa Sterpeto paleoseismological trench was dug to disclose the fault zone imaged by

501   the geophysical investigations (Fig. 6). The trench walls exposed 11 depositional units. The oldest

502   continental unit, formed by gravels of the Citerna synthem (unit 11), is juxtaposed by faulting to the

503   younger sedimentary sequence of the Anghiari sub-synthem (units 7, 8, 9 and 10), colluvium

504   containing paleosols (unit 2, 3, 4, 5 and 6) and anthropogenic deposits (unit 1). The detailed

505   description of the stratigraphy is reported in the supporting information Text S3.

506

507

Fig. 6. Interpreted orthophotomosaic of the north-west wall of the Villa Sterpeto trench. The white squares correspond to the location of the pictures in fig. 8. The stereoplot, from left to right, represents respectively: results of AMS analysis (square, triangle and circle are maximum, intermediate, and minimum susceptibility axes, respectively); bedding attitude; and fractures attitude. The rose diagram shows the fracture attitude measured on the trench wall (in orange) and bench (in black).

515

The fault affects the entire trench wall up to the base of the topmost unit (unit 1), with a sharp contact, 10-20 cm-wide thickening in the upper part, dipping 50° toward NE (Fig. 7). In particular, the fault mean attitude is 052/52 (dip direction/dip) with variable value of dip ranging from 48 to 60 degree; the slip vector measured on striae trends 85°N and the plunge is 57°. Based on its lithological and chromatic features, the fault zone is divided into a stiff light brown fine-grained, organic rich fault zone (FZ1) and a whitish fault zone made of crushed gravel, outcropping in the lower part of the trench (FZ2). Locally, FZ1 and FZ2 are separated by a shear surface. Two samples of FZ1 bulk sediments were collected for radiocarbon dating (VS_C07 and VS_C08), providing ages of 46 - 117 CE and 4,315 - 4,050 BCE, respectively (Tab. 1).

In the hanging wall of the fault, the colluvial unit 4 forms four coarse-grained wedge-shaped bodies of material colluviated from unit 11 that interfinger with unit 5 (CW1-4 in Fig. 7). An additional wedge-shaped fifth body (CW5?) is partially visible in the lowest part of the trench wall. The four wedge-shaped bodies are stacked with similar shape and size. Their geometric settings, suggests an accumulation controlled by episodes of footwall exhumation. A mechanism able to explain all those features is the rapid formation of a scarp due to surface faulting events, and consequent accumulation of scarp-derived colluvial wedges in proximity of the fault due to scarp degradation (colluvial wedge model in McCalpin, 2009).

Based on the gravel fabric, it is possible to estimate a maximum wedge thickness of 45 cm with large uncertainty. The thickness of the wedge CW5 is uncertain since it is partially buried.

CW4 and CW3 have comparable lateral extension and their tip is lying on darker and fine-grained horizons. Particularly, CW3 overlays a 5 to 10 cm-thick weak paleosol, which possibly corresponds to the topographic surface immediately before the onset of coarse-grained colluvial sedimentation (Fig. 7c). Between CW3 and CW4 an open fissure branches from the main fault zone and is infilled with the same material of the wedge.

CW2 is steeper and thicker near the fault, with a few cm-thick fine-grained layer, possibly corresponding to a weak soil horizon, at the base of its tip. CW 1 is the smallest wedge and does not show a clear fine-grained horizon at its base. All the wedges are faulted.

In order to constrain the age of each wedge formation, and thus of related episodes of footwall exhumation, we collected samples for radiocarbon dating of the fine-grained organic layers of unit 5, at their bases, paying attention to collecting the most organic layers. Due to the lack of charcoals in units, the dating was performed on the bulk organic fraction contained in the sediments. Moreover, we sampled the units 6 and 3 which are the lowermost and uppermost boundaries of the entire colluvial   unit,   respectively.

 The hanging wall depositional sequence from unit 6 to 10 is tilted against the fault. The mean layer attitude in the trench is 265/12 (dip direction/dip). The dip of the boundary between units 6 and 7 becomes progressively steeper toward the fault, from 5° to 25°, suggesting syn-depositional back-tilting. In the nearby of the trench, in the hanging wall of the fault, the Citerna synthem is tilted up to 35° towards the west. This geometrical setting can be interpreted as large-scale, fault-related hanging wall back-tilting that created accommodation space for the deposition of units 1 to 5.

To measure the displacement of the fault we used the buried paleosol of unit 6, the top of which should correspond to an ancient topographic surface. The top of unit 6 is displaced about 4 m vertically (5.1 m along-dip slip) with respect to the nowadays topographic surface. Since the topographic surface may have been reshaped, this should correspond to the minimum fault displacement accumulated since the age of unit 6 (23,126 - 22,626 BCE, sample VS_C01) (Tab. 1).
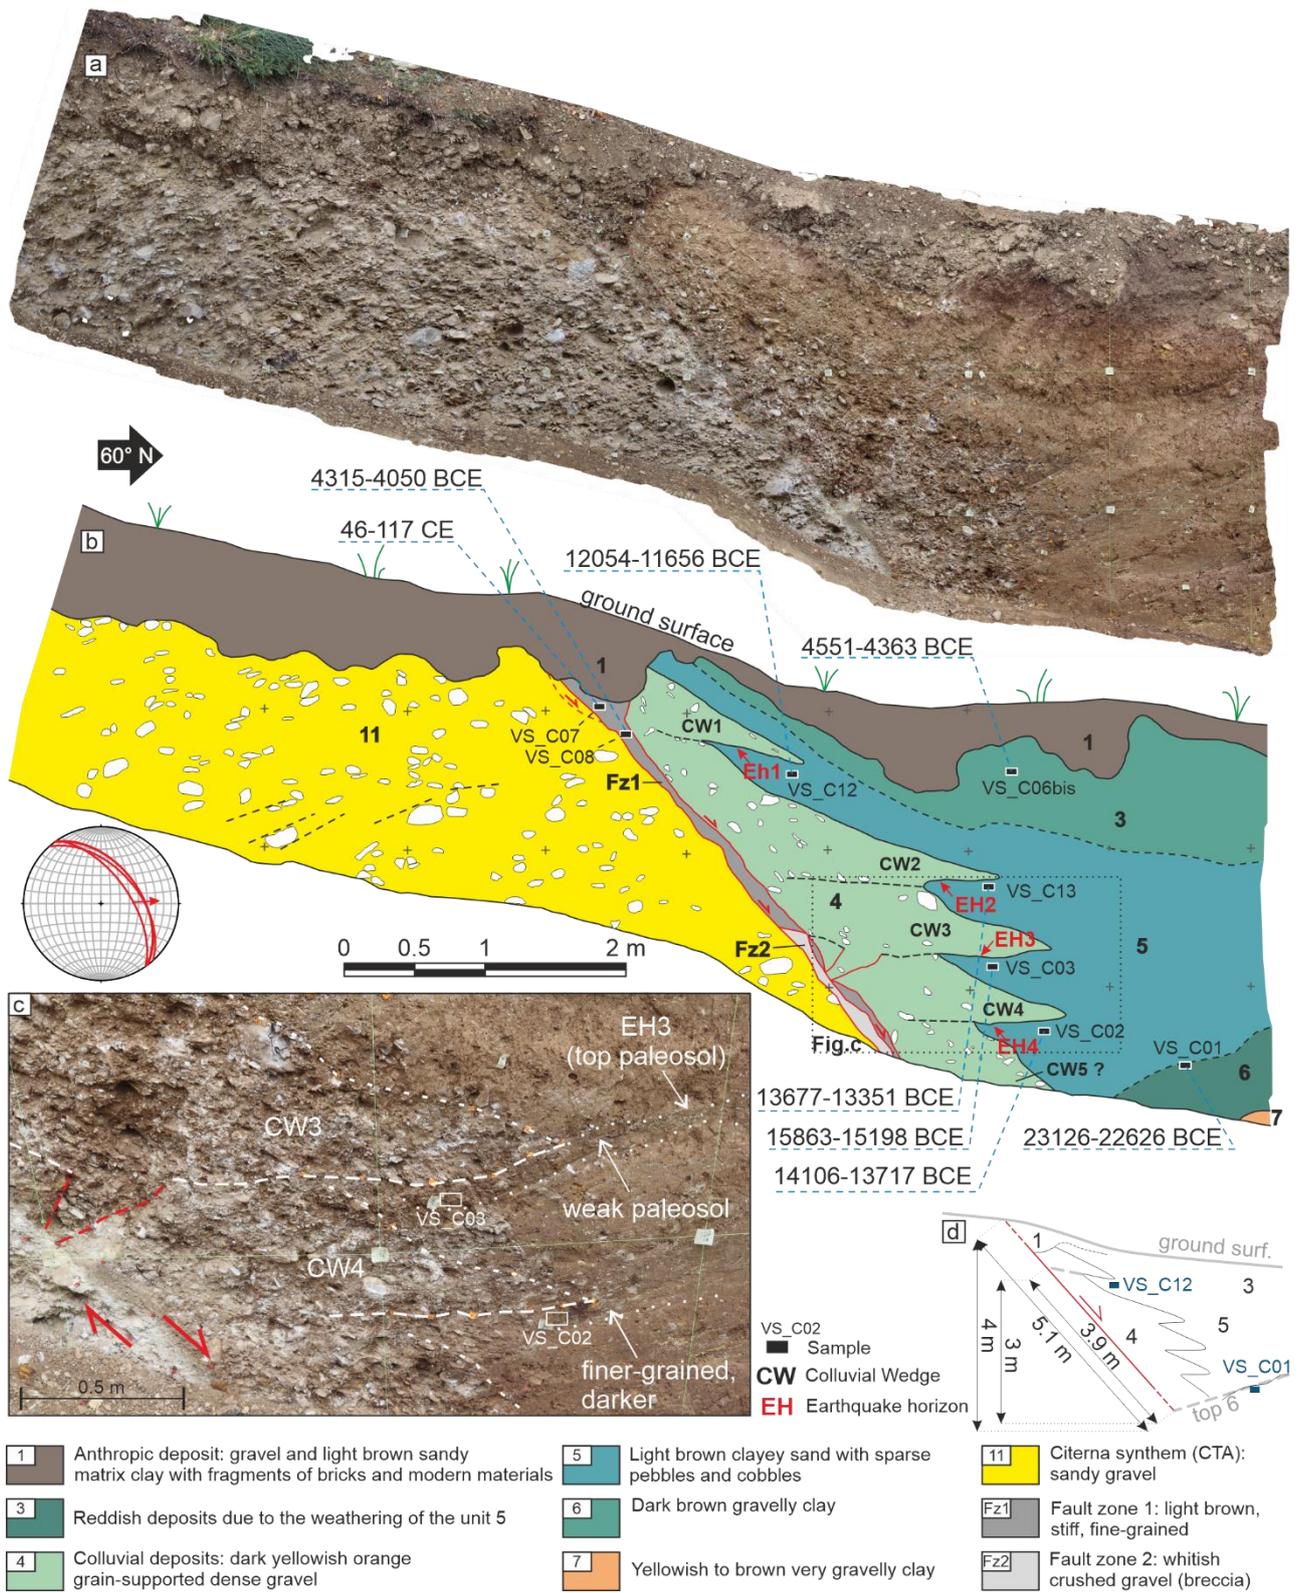

Fig. 7. Detailed view of the fault zone of the Villa Sterpeto trench (a); interpretation of the fault zone of the Villa Sterpeto trench, with the age of the samples (b); detail of the colluvial wedges CW3 and CW4 and the corresponding

earthquake horizons (c); simplified scheme of displacement measure to compute the slip rate (d); The attitude of the fault

and the corresponding slip vector are shown in the stereo plot.

4.2.3. Fissures and other secondary features

Many fractures, fissures and other soft-sediment deformation affect units 9 and 8 (Fig. 6). A sharp

boundary separates unit 9 from the underlying massive gray clays of unit 10 (Fig. 8a). In general, the

fissures have an aperture in the order of 0.5 to 2 cm and are infilled with clay material from unit 10.

Other fractures, without measurable aperture, are highlighted by a cm-sized bleaching halo,

particularly evident in the red-colored unit 8. Unit 9 is pervaded by both layer-parallel and layer-

perpendicular (or oblique) fissures (Fig. 8b). Most of them are confined within unit 9, while some of

them cut through both units 9 and 8 perpendicularly to the bedding (Fig. 8c). Layer-perpendicular

fractures with bleaching halo prevail in unit 8. When observed on the SE-facing wall of the trench,

the layer-perpendicular fissures, and fractures dip apparently to the NE, as they are tilted with the

hosting sedimentary beds (Fig. 6). Nevertheless, the true dip is nearly vertical; the measured strikes

cluster around values of 70±10° (stereonet in Fig. 6). In map view (on the bench floor, Fig. 8d), some

fractures form approximately conjugate systems, with acute angles of 45-60°. Overall, the strikes

measured on the trench wall and on the bench floor are dispersed between 30° and 120°, with a main

cluster at 70±10° (the bisector of the acute angle) and two secondary clusters at 105±5° and 50±15°

(rose diagrams in Fig. 6).

The boundary between units 8 and 9 is affected by soft-sediment deformation of different

types. At places, flames of clay injections fed by fissures from unit 9 intrude into the bottom part of

unit 8, forming "jester hat-like features" (Fig. 8b). Often, the stratigraphic transition is characterized

by a 10-15 cm-thick breccia layer formed by angular clasts from unit 8 in the matrix of unit 9, which

indicates mixing along the boundary between the two units. The breccia layer can intrude slightly

into the overlying unit 8, forming flame structures (Fig. 8e), or can be coated by clay material, forming

587 pseudo-nodules (Fig. 8f).

588 The interpretation of these features as due to earthquake-induced ground shaking would give insights

589 on the recurrence of strong earthquakes on the Sansepolcro basin fault system, as argued in the

590 discussion section.

591
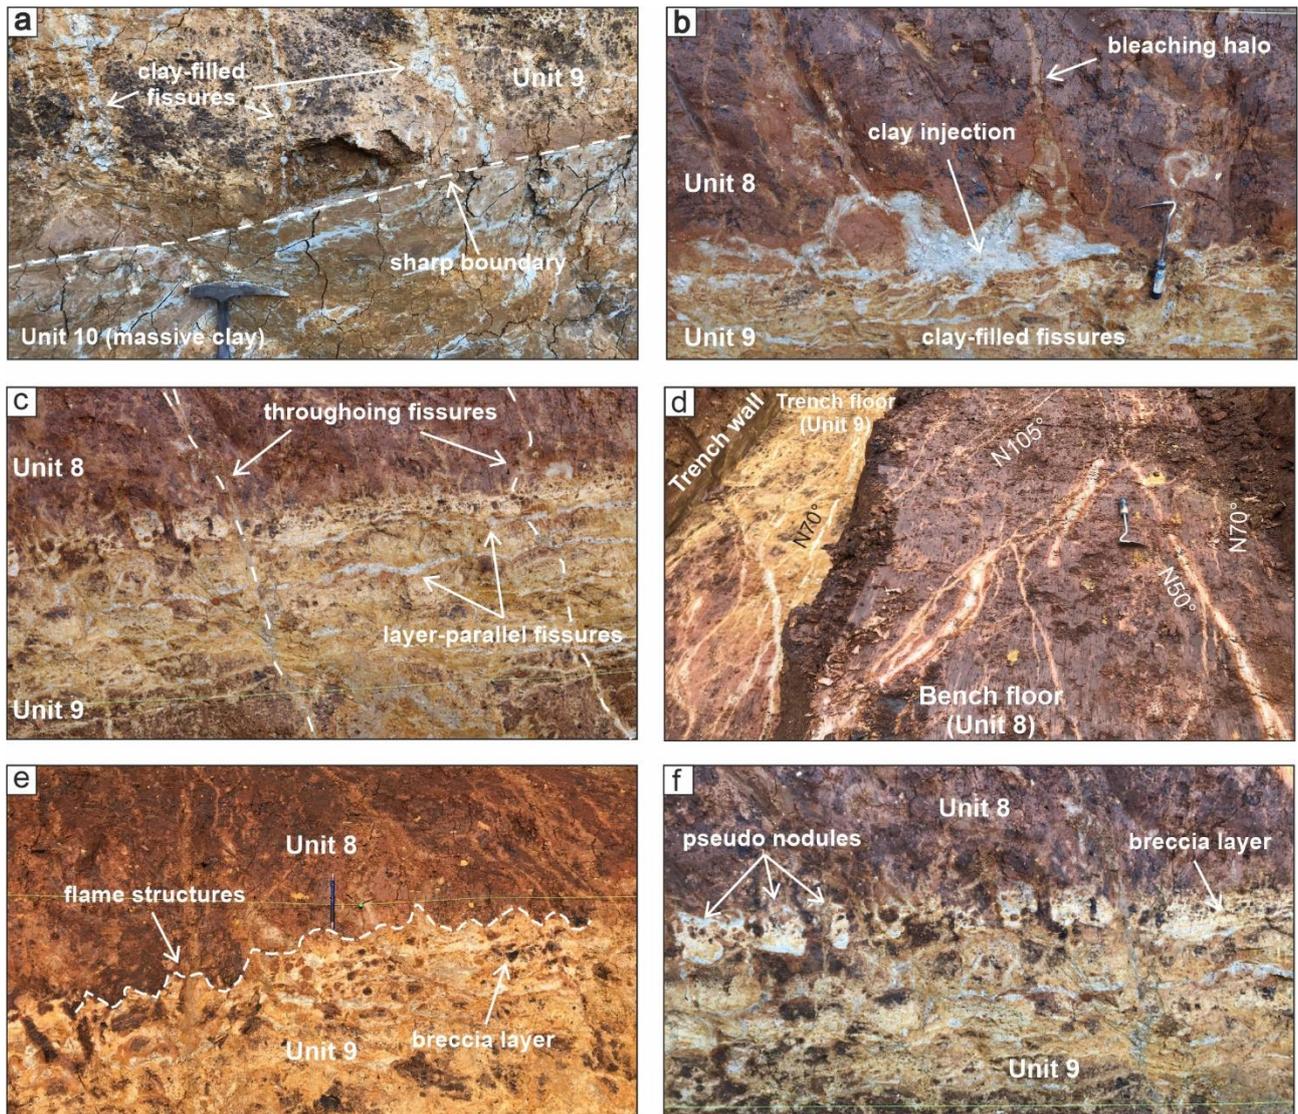

593 Fig. 8. Detailed views of soft-sediment deformation within units 8 and 9. Clay injections and clay-filled fissures

594 are sourced by unit 10. Location in Fig. 6. Fig. (d) is an oblique view to NNE of the trench and bench floors.

4.2.4. Anisotropy of magnetic susceptibility

The results of the AMS analyses are reported in the supporting information (Figure S5 and Table S1). The mean susceptibility on the sites collected in the clays varies from 139 to 217 e-6 SI, while the sites collected in the paleosol and in the colluvial unit containing the wedges have higher susceptibility, from 888 to 7162 e-6 SI. All sites are characterized by a well-defined AMS tensor. The shape of the ellipsoids, T, varies from weakly oblate (ANGH01, 02, 04, 05) to strongly prolate (ANGH03) and one site is triaxial (ANGH08). The degree of anisotropy, P_j, indicates that the sites vary from weakly anisotropic (4% of ANGH01) to strongly anisotropic (43%, ANGH08), approaching the fault trace. The orientation of the k_{max} axis, that can represent the direction of the magnetic lineation (k_{max}/k_{int}), is mostly shallowly oriented NE-SW, and it is orthogonal to the foliation plane (k_{int} / k_{min}), oriented NW-SE, steeply dipping to the NE. The anisotropy data suggest that a primary sedimentary fabric has been overprinted by an incipient to intense tectonic fabric as confirmed by the evolving AMS tensor shape from purely oblate farther from the fault to oblate and prolate approaching the fault.

The magnetic foliation orientation is mostly NW-SE, thus sub-parallel to the fault plane. The magnetic lineation is orthogonal to the ATF and parallel to the NE–SW-oriented direction of extension revealed by both regional active stress field (Montone et al., 2016) and Quaternary strain indicators (Lavecchia et al., 2022). These results are comparable with the stretching direction inferred by Maffione et al. (2012) through the AMS analysis of the Lower Pleistocene Fighille synthem at a nearby site, south of the Anghiari ridge (their site SANS).

In summary, the AMS indicates continuous extension across the stratigraphy exposed in the trench. When compared with data from the literature, our results suggest that in the study area an extensional stress field has been continuously active since the Early Pleistocene.

4.3. Todari site

The Todari roadcut was dug across a secondary strand of the Micciano section. The outcrop exposes 7 units, a NE-dipping main normal fault zone and a sub-vertical antithetic splay (Fig. 9). The main fault juxtaposes an Early-Middle Pleistocene unit, part of the Citerna synthem, from a Holocene succession formed by, from the bottom to the top, a paleosol (unit 6), clayey palustrine deposits (unit 5), clayey-sandy colluvial units (unit 2 to 4) and the present-day soil (unit 1). An additional unit is the infill of a fissure topped by unit 4 (FF, filled fissure).

The detailed description of the stratigraphy is reported in the supporting information Text S3.
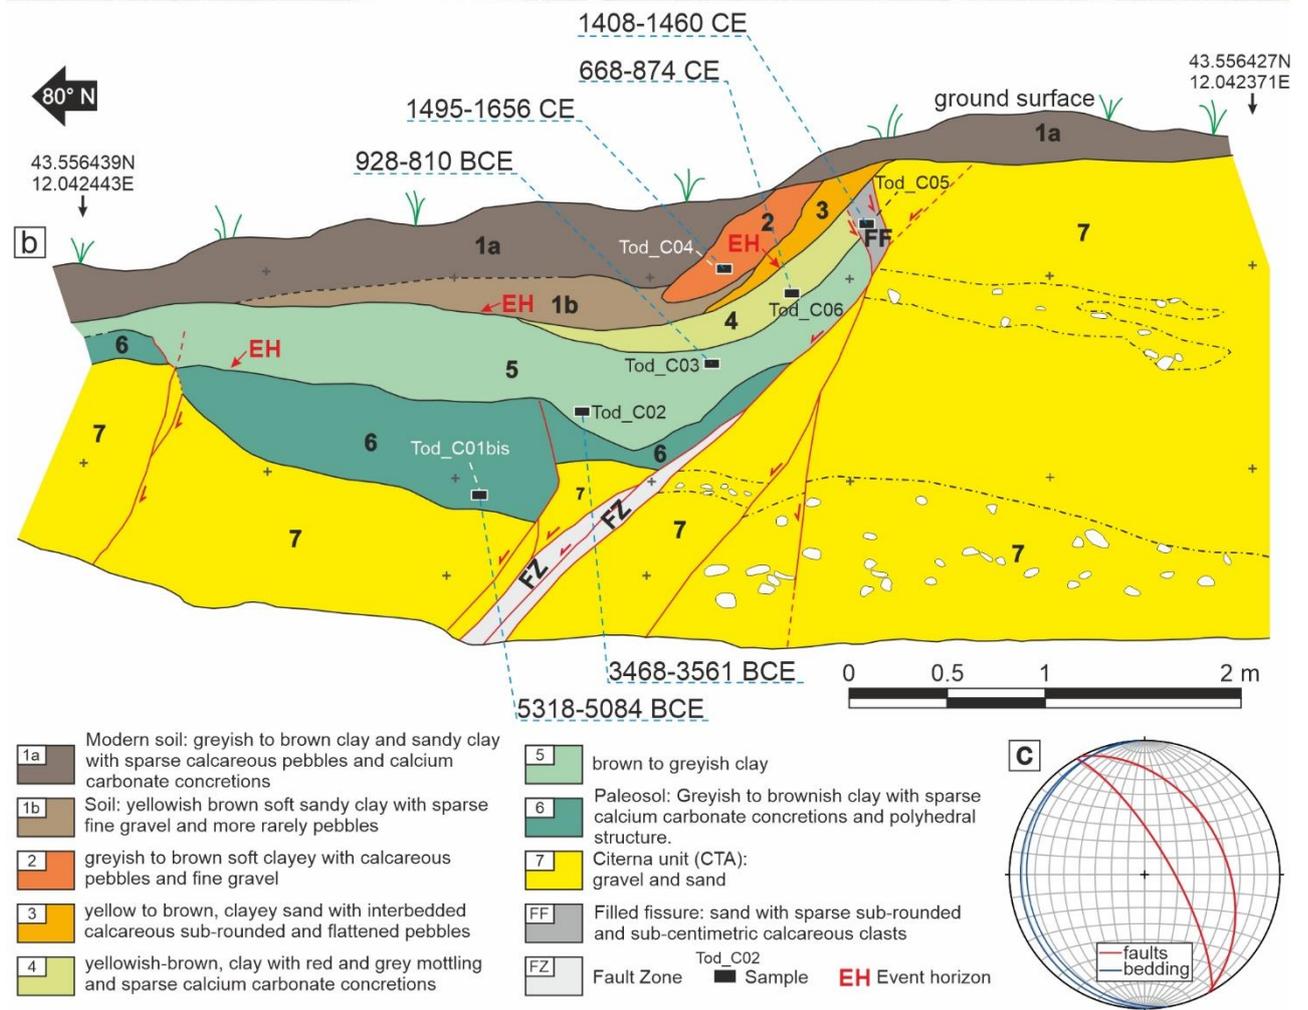

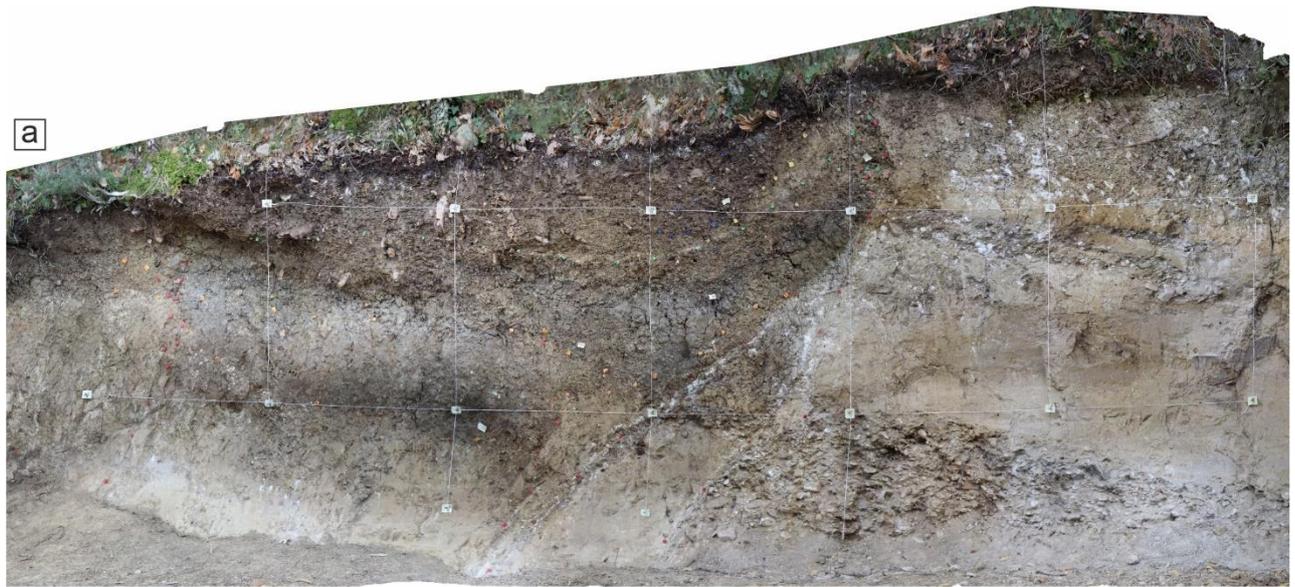

Fig. 9. Detailed view of the Todari roadcut (a); interpretation of the Todari roadcut, with the age of the samples (b); the attitude of the fault and bedding are shown in the stereo plot (c).

4.3.1. Primary tectonics features

631

632   The Todari roadcut is characterized by several synthetic normal fault splays dipping 40° to

633   50° towards NE. The main fault zone (FZ in Fig. 9) is composed of fault brecciated sand coming

634   from the faulting of unit 7. The hanging wall of the main fault zone includes two synthetic splay

635   dipping from 60° to 80° toward NE and connected to the principal fault in the upper part. Another

636   synthetic splay displaces the boundary between units 6 and 7 in the hanging wall of the main fault.

637   This fault dips 50° at the bottom of the trench and becomes progressively steeper upwards, up to

638   overturn close to the surface. Unit 4, 5 and 6 are faulted and dragged against the main fault zone,

639   whereas units 3 and 2 are deposited after the last apparent deformation episode.

640   A sub-vertical antithetic splay, located in the hanging wall at ~2 m from the main fault,

641   displaces by 20 cm the boundary between units 6 and 7.

642

4.4. Anghiari sites A and B

The site A trench was excavated across the trace of the Anghiari-Motina fault section, while the site B trench was excavated in the hanging wall of the fault. The site B trench cut across the MTC synthem and provided constraints on the stratigraphy of the hanging wall, which helped us in constraining the displacement accumulated after the deposition of the MTC (Fig. 3). The orthophotomosaic of the site B trench and its stratigraphic description are provided as supporting information (Fig. S4). In the following, we describe the site A trench, which is characterized by 12 depositional units and 3 high-angle tectonic contacts (Fig. 10). The main tectonic contact downthrows to the NE the stratigraphic succession older than unit 2. The youngest unit (unit 1) is an anthropogenic backfill. Units 2 to 8 are colluvial deposits, the youngest of which (unit 2) is historical (contains pottery shards). Unit 9 is a remnant of an alluvial terrace. Unit 10 is made of gravel and sand belonging to the CTA synthem. The clayey unit 11 is the oldest unit, possibly belonging to the Fighille synthem.

The detailed description of the stratigraphy is reported in the supporting information Text S3.

4.4.1. Primary tectonics features (site A)

The site A trench wall exposes three barely visible fault zones (FZ1, 2 and 3 in Fig. 10). Between FZ1 and FZ3 the depositional sequence and the faults are cut by a gravitational sliding surface (green line in Fig. 10) with slip direction to the NE (i.e., downslope). The gravitational sliding postdates the faults and is covered by unit 2 (containing reworked pottery shards of VII-XIV century CE).

The main fault zone (FZ1, Fig. 10) is formed by two nearly parallel high-angle fault strands downthrowing by a minimum of 1.75 m to the NE the contact between units 4b and 5. In the hanging wall of the main fault there are two colluvial units (3a and 3b). Unit 3b is wedge-shaped and thickens

close to the fault, suggesting that its sedimentation can be related to the fault. It is not clear if unit 3b

is faulted or simply rests on the fault surface. The geometry of unit 3a is undetermined, as its western

edge is cut by the gravitational sliding surface and its upper part is truncated by unit 2. The possible

meaning of units 3a and 3b in relation to the fault activity will be discussed in the next section. The

fault zone is sealed by the gravitational sliding surface and by unit 2, which has an age not older than

VII-XIV centuries CE, or younger, on the basis of the findings of reworked pottery shards.

A sharp, high-angle lateral contact between unit 7 and unit 11 (FZ2, Fig. 10), located 3 m

upslope FZ1, can be interpreted as a tectonic contact sealed by the upper part of unit 7.

The third fault zone (FZ3, Fig. 10), formed by two antithetic strands downthrowing by ~10 cm to the

SW the base of unit 4b, is sealed by unit 2.

In order to constrain the fault prosecution at depth, we acquired an ERT along the trench floor. The

ERT profile reported in Fig. 10 was obtained by the joint inversion of the Wenner and dipole-dipole

acquisitions. The contact between the gravels of the Citerna synthem and the underlying clays and

silts is evident in the first meters of the profile. A sharp lateral resistivity variation, from <40 Ωm to

40-50 Ωm is present in the center of the profile and corresponds to the down-dip continuation of FZ2.

The down-dip continuation of FZ1 is not particularly evident but can be the cause of the eastward

lateral transition to lower resistivity values from 40-50 Ωm to <15 Ωm. There is no evidence in the

profile of FZ3, probably because the limited displacement does not produce a lateral resistivity

variation.
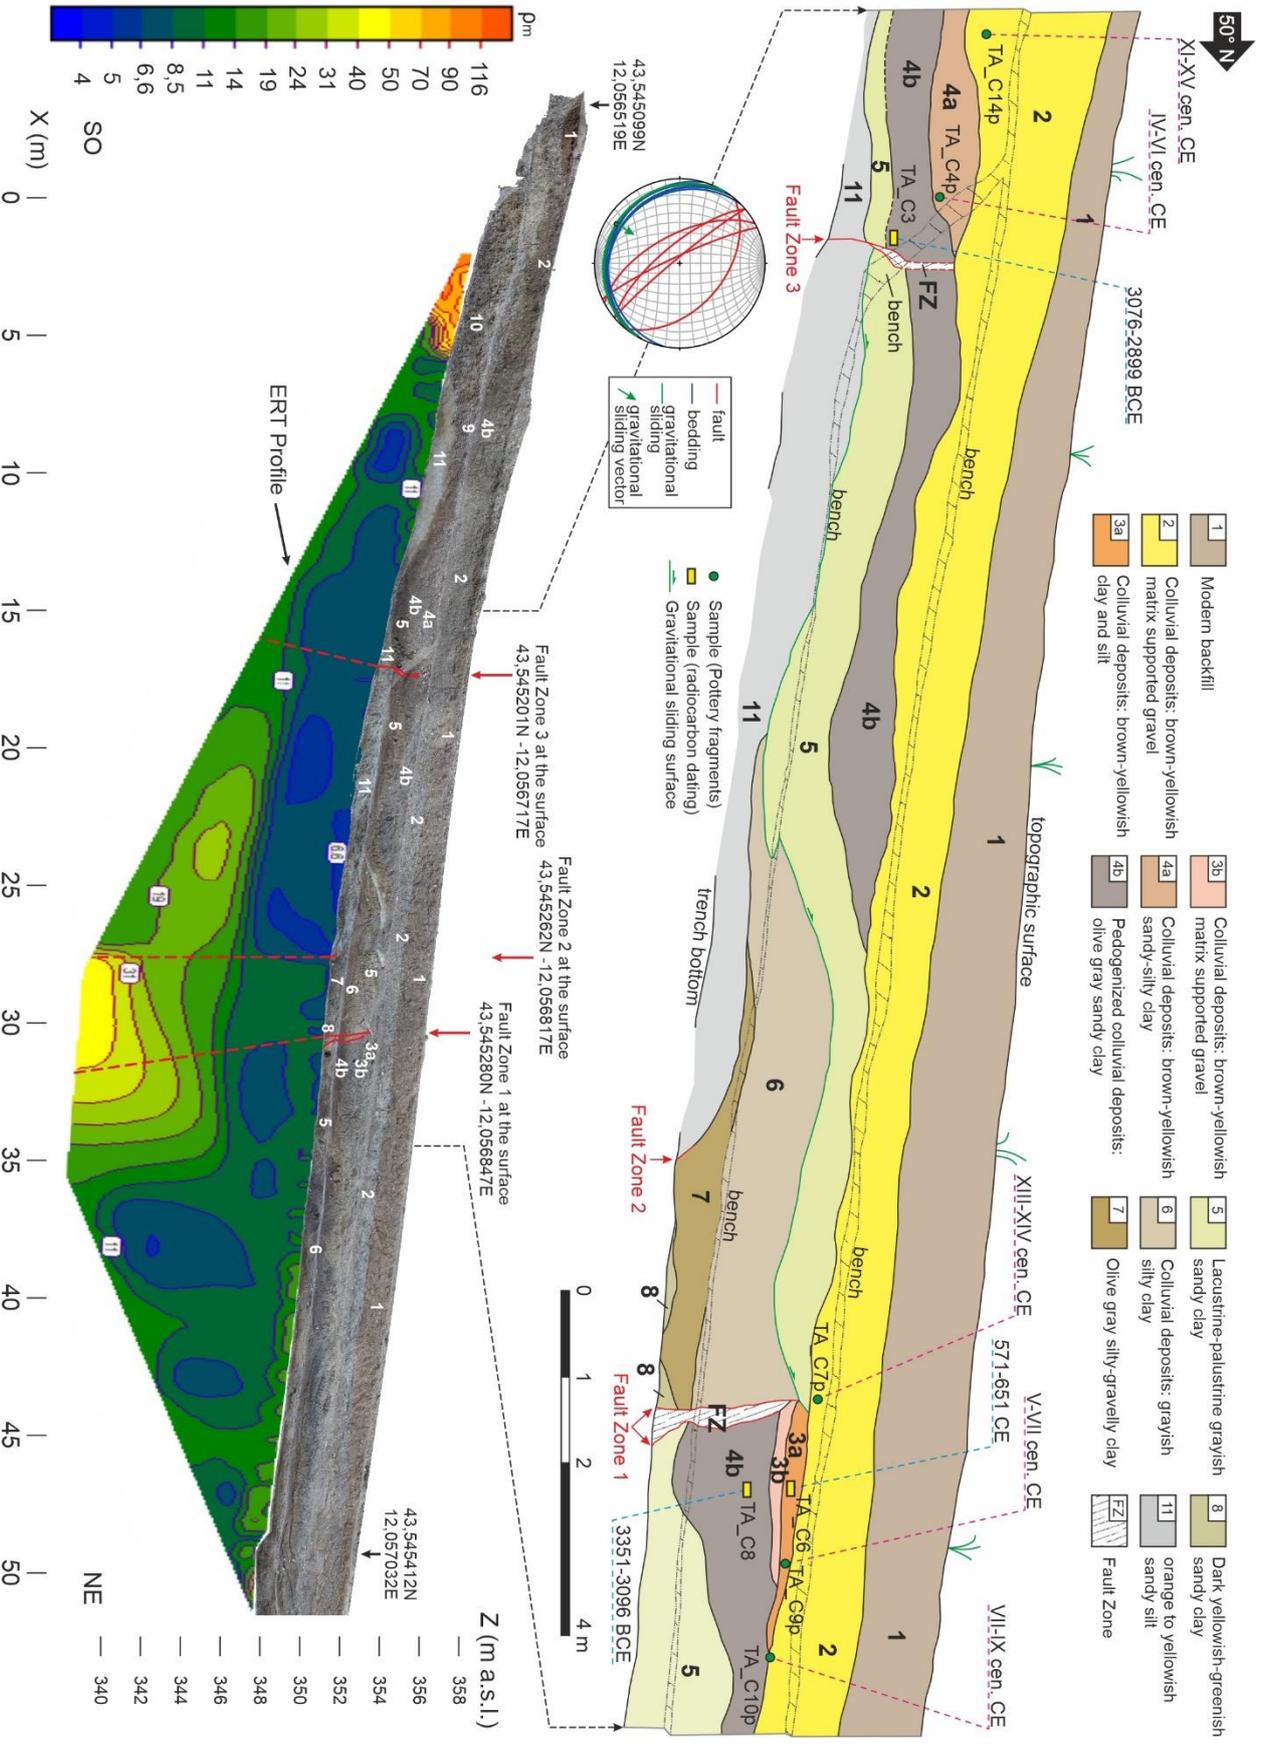

688 Fig.10. Orthophotomosaic of the Anghiari site A trench and ERT profile acquired along the trench floor with interpreted

689 down-dip continuation of the fault zones (bottom) and interpreted log of the stratigraphy and main fault zones with age

690 of samples (top). The attitude of bedding, gravitational sliding surface, faults and slip vectors are shown in the stereoplot.

5. Discussion

5.1 Paleoearthquakes

At the Villa Sterpeto site the presence of five stacked colluvial wedges (CW in Fig. 7) against

the fault suggests the occurrence of as many discrete and recurrent surface faulting earthquakes. Each

earthquake is supposed to have produced a coseismic fault scarp at the surface (free face). The erosion

of the exhumed scarp would have caused the deposition of colluvial material in the hanging wall of

the free face, on top of the downthrown ground surface. This hypothesis is supported by the presence

of fine-grained, moderately organic layers below the wedges, particularly developed beneath CW3

(i.e., the weak paleosol at the base of CW3, see Fig. 7c). Those fine-grained organic layers can be

interpreted as the earthquake horizons (hereinafter EH), i.e., the topographic surface at the time of

the surface faulting earthquakes. Moreover, the termination of the open fissure located below CW3,

possibly corresponds to the boundary between CW3 and CW4, i.e., the earthquake horizon EH3 (see

Fig.   7).

 In addition, a fault activity during the colluvial accumulation is required to explain the formation of

the space necessary for the stacking of the wedges in the hanging wall of the fault and their later

faulting. Based on the above considerations, we interpreted the colluvial wedges as tectonic in origin

.

Thanks to the radiocarbon dating, we tried to constraint the age of each EH and therefore

hopefully the closest *pre faulting* age of each earthquake. The reconstructed chronology of the surface

faulting earthquakes is reported in Fig. 11 and in Tab. 2.

CW1 was deposited immediately after 12,054 - 11,656 BCE (sample VS_C12, collected

below the wedge), and before 4,551 - 4,363 BCE (sample VS_C06bis), collected within unit 3).

Therefore, the age window for E1VS is between 12,054 and 4,363 BCE. CW2 was deposited immediately after 13,677 - 13,351 BCE (sample VS_C13, collected below the wedge), and before 12054-11656 BCE (sample VS_C12, collected above the wedge). Therefore, the age windows for E2VS is between 13,677 and 11,656 BCE.

Because of the out of sequence ages of the samples VS_C03 and VS_C02 we advanced two different hypotheses concerning the age of the events E3VS and E4VS:

1) Hypothesis 1 excludes sample VS_C03 due to significant age inheritance, beyond the calibrated age uncertainty, caused by contamination from old material reworking. CW3 and CW4 would have deposited both between 14,106-13,1717 BCE and 13,677-13,351 BCE (samples VS_C02 and VS_C13). Therefore, E3VS and E4VS both occurred between 14,106 and 13,351 BCE.

2) Hypothesis 2 excludes sample VS_C02, thus assuming contamination by young carbon that provides an age younger than the overlying sediments. CW3 would have deposited immediately after 15,863 - 15,198 (sample VS_C03) and before 13,677 - 13,351 BCE (sample VS_C13). CW4 would have deposited after 23,126 - 22,626 BCE (sample VS_C01) and before 15,863 - 15,198 (sample VS_C03) (Fig. 7). Therefore, E3VS occurred between 15,863 and 13,351 BCE, while E4VS occurred between 23,126 and 15,863 BCE. Since the base of the wedge 5 and its chronological relationship with respect unit 6 (sample VS_C01, 23,126 - 22,626 BCE) are buried below the trench floor, it is not possible to exclude that, in the time interval relative to E4VS (23,126 - 15,863 BCE), more than one earthquake has occurred. Hypothesis 1 involves a cluster of earthquakes in a short time window, while hypothesis 2 provides a more regular slip history. Hypothesis 1 appears more reasonable, because it implies the discard of a sample (VS_C03) contaminated by old carbon, which has been demonstrated to be likely (Rockwell et al., 2022). Nevertheless, sample VS_C03 was collected in one of the most evident buried paleosol within the colluvial unit. This makes the sample more reliable than others. On the other hand, we cannot exclude that younger carbon could have contaminated sample VS_C02. Since earthquake

clustering is quite common in the Apennines (as Chlorine 36 studies suggest, e.g., Benedetti et al., 2013; Cowie et al., 2017; Mildon et al., 2022; Schlagenhauf et al., 2011), there are no particular criteria to prefer one hypothesis to the other.

Since CW1 is faulted, there is evidence of at least an earthquake younger than E1_VS. Such event(s) would be compatible with the tectonic folding of the unit 3 bottom (4,551 – 4,363 BCE, sample VS_C06bis). According to the age of the organic material trapped and sheared within the fault zone (sample VS_C08) this earthquake could be post 4,315 - 4,050 BCE.

At the Todari roadcut, the restoration of the tectono-stratigraphic setting allowed us to reconstruct three surface faulting events (Fig. 12). The oldest event (earthquake E3 Tod) caused the displacement of the boundary between units 6 and 7 along the synthetic and antithetic splays in the hanging wall of the main fault (Fig. 12b). This earthquake occurred after 5,318 - 5,084 BCE, age of unit 6 (sample Tod_C01bis) and before 3,468 - 3,561 BCE, age of unit 5 (sample Tod_C02). The net slip measured on the synthetic splay was 18 cm, with a minimum net throw of 14 cm. This can be considered as the minimum surface displacement of the earthquake because some slip could have occurred along the main fault, which shows no visible piercing points (Fig. 12b). After E3 Tod, an erosional event, possibly caused by water running parallel to the fault, reshaped the top of unit 6, erasing the evidence of slip along the synthetic fault (Fig. 10c). The age of E3 Tod could be comparable to the age of the earthquake faulting CW1 at the Villa Sterpeto trench.

Earthquake E2 Tod occurred after 928-810 BCE, age of unit 5 (sample Tod_C03) and before 668-874 CE, age of unit 4 (sample Tod_C06) (Fig. 12e). This event caused a minimum net slip along the main fault of 52 cm (minimum throw of 35 cm), including the dragging of units 5 and 6 and rotation of the high angle splay in the upper part of the main fault (Fig. 12e). The subsequent erosion of the fault scarp caused the deposition of a colluvial wedge (unit 4) (Fig. 12f). The most recent earthquake (MRE Tod) caused the opening of a fissure in correspondence of the rotated synthetic splay and the dragging of units 4, 5 and 6 (Fig. 12g). The minimum net displacement along the main fault was 35

763 cm (minimum throw of 23 cm). After the MRE, because of the erosion of the scarp, the fissure was

764 filled and another colluvial wedge was formed (unit 3) (Fig. 12h). The MRE occurred after 668-874

765 CE, age of unit 4 (sample Tod_C06) and immediately before 1408-1460 CE, age of the infilling of

766 the fissure (sample Tod_C05). The fissure infill is rich in organic matter. It is likely that the fissure

767 was infilled by material from the soil at the time of the surface faulting. Therefore, the age of the infill

768 should be close to the occurrence of the event. The minimum cumulative net slip of the last three

769 earthquakes is 1.05 m (minimum cumulative throw of 0.72 m) accumulated since 5,318 - 5,084 BCE.

770 The age constraints bracketing the event windows for the Villa Sterpeto and Todari sites are

771 summarized in Fig. 11a and Tab. 2. Using the Boundary-Zero Boundary model, we performed a

772 Bayesian analysis in OxCal v4.4.4 at the Villa Sterpeto site skewing the age of the earthquakes thanks

773 to the samples collected immediately below the colluvial wedges, i.e., within the earthquake horizons.

774 At the Todari roadcut we used the same methodology to constrain the age of MRE_Tod close to the

775 age of the infilling of the fissure (sample Tod_C05); the age of E2_Tod close to the deposition of the

776 colluvial wedge corresponding to unit 4 (sample Tod_C06); and the age of E3_Tod close to the age

777 of the base of unit 5. The obtained ages are reported in Fig. 11b.

837   3561 BCE and 928-810 BCE unit 5 is deposited; e) E2_Tod (between 913 BCE and 702 CE) unit 5 and 6 are displaced

838   by the main fault and its antithetic splay and dragged by the main fault. The top of unit 5 is reshaped by erosional events;

839   f) after E2_Tod (between 668 and 874 CE) the colluvial wedge corresponding to unit 4 is deposited; g) MRE_Tod

840   (between 702 and 1470 CE) caused the dragging of unit 4, 5 and 6 and the opening of a fissure; h) After MRE_Tod and

841   close to the 1408-1460 CE the fissure is infilled and the colluvial wedge corresponding to unit 3 is deposited; i) Around

842   1490-1656 CE unit 2 is deposited; j) nowadays configuration.

843

844   At the Anghiari site A the colluvial wedge 3a, possibly faulted, suggests the occurrence of one or two

845   surface faulting earthquakes occurred between 3,351 - 3,096 BCE and XIV century (or shortly after,

846   considering that the pottery shards are reworked), the ages of unit 4b and 2, which are comparable

847   with the time windows of the youngest events of the Todari roadcut site.

848   The youngest recognized earthquake occurred in historical time (938 - 1472 CE, Fig. 11b). Two

849   historical earthquakes hit the Sansepolcro basin in that time interval or close to it, the 1458 and 1489

850   earthquakes (Fig. 2), with the 1458 being the strongest (epicentral intensity VIII-IX, Mw 5.8).

851   Therefore, the youngest surface faulting event might correspond to one of these two earthquakes,

852   possibly the 1458 event, which fit the time window of the surface faulting event. Unfortunately, the

853   1458 event is poorly constrained by macroseismic data. The Anghiari town, the nearest town to the

854   studied fault, has no macroseismic information on both the 1458 and 1489 events. The 1458

855   earthquake produced damages of intensity VIII-IX in both Città di Castello, in the southern edge of

856   the basin, and in Sansepolcro, 15 km north of Città di Castello and only 7.5 km east of Anghiari.

857   Damage of intensity VII-VIII was documented for a locality sited 13 km south of Città di Castello.

858   In this context, it seems unlikely that the earthquake did not damage Anghiari, at a distance of 17 km

859   to Città di Castello and 7.5 km to Sansepolcro, within the same sedimentary basin. The lack of

860   macroseismic information in Anghiari is possibly due to a gap in the historical documentation.

861   Therefore, we suggest that the 1458 earthquake was caused by reactivation of the Anghiari fault, and

862   possibly of the entire Anghiari-Città di Castello main fault.

863   In summary, combining the data from all the paleoseismological investigations, we recognized nine

864   different earthquakes in the last 22 ka and an additional one possibly older than 25 ka. The most

865   recent event possibly corresponds to the 1458 historical earthquake. These events broke the surface

866   along the Micciano section of the Anghiari fault (Villa Sterpeto site), the secondary splay located in

867   its footwall (Todari roadcut) and, at least the two most recent earthquakes also could have broken the

868   Anghiari-Motina section (Anghiari site A). These sites might show two different parts of the same

869   seismic history: i) the oldest part (22,000 to 4,500 BCE) at the Villa Sterpeto site; ii) the youngest

870   part (5,200 BCE to 1,437 CE) at the Todari roadcut and Anghiari site A sites.

871

872   **5.2 Recurrence intervals and coefficient of variation**

873   The mean recurrence time interval has been estimated from our paleoseimological earthquake

874   time series and its uncertainties in dating, with a Monte Carlo simulation approach through the tool

875   RP included in the FISH tools package for seismic hazard assessment (Pace et al., 2016, code

876   available at http://fault2sha.net/wp-content/uploads/2020/07/FiSHvers1.02.zip). Given the time

877   windows of a series of paleo-events the RP tool produces a number of earthquake catalog simulations

878   and computes the average recurrence time and its coefficient of variation (CV), namely the standard

879   deviation of the recurrence times over their mean. CV is a critical parameter for time-dependent

880   seismic hazard estimates, it is often poorly constrained (e.g. Ellsworth et al., 1999; Visini and Pace,

881   2014), and small differences in the values can lead to large differences in earthquake probability

882   evaluation.

883   In tab. 3 are reported the computed values of mean recurrence time intervals based on the constrained

884   age of the paleoearthquakes for both the earthquake ages hypotheses and considering both the time

885   windows between each couple of samples (see Fig. 11a) and the earthquakes age obtained using

886   OxCal v4.4.4 (see Fig. 11b).

887   Considering that, in hypothesis 2 (quasi-periodic slip history), within the time windows related to the

888   event E4_VS more than one earthquake may have occurred, this event has been excluded from the

889   computation. While, for hypothesis 1 (clustering) all the events have been considered.

890   Using only the age of the samples as constraints for the age of the earthquakes, the mean recurrence

891   time interval ranges between 2495 years and 3104 years, with a CV of 0.94-0.65 (for hypothesis 1

892   and hypothesis 2 respectively).

893   Using the earthquake time windows from the Bayesian model computed in OxCal, the mean

894   recurrence time interval ranges between 2562 years and 3230 years with a CV of 0.92-0.62 (for

895   hypothesis 1 and hypothesis 2 respectively).

896   Both the Recurrence time interval and the CV are affected by the choice of the hypothesis, while they

897   are not affected by the ages used as input in the computations (age of the samples rather than OxCal).

898   In general: i) for hypothesis 1 the recurrence time interval is shorter, but the CV is higher, indicating

899   a non-periodic behavior. Ii) for hypothesis 2 the recurrence time interval is higher, but the CV is

900   lower, indicating a more periodic behavior.

901

Paleoearthquakes age constraints	Paleoearthquekes age hypothesis	Recurrence interval (years)	Coefficient of variation
Age of the samples	1	2495	0.94
Age of the samples	2	3104	0.65

5.3 Slip rates

The minimum fault displacement measured at the Villa Sterpeto site (5.1 m accumulated since

the age of unit 6, i.e., after 23,126 - 22,626 BCE) provides an average post-25 ka BP slip rate of 0.2

mm/yr. This slip rate is apparent, as it includes both closed and open seismic cycles. In order to

consider only closed seismic cycles, the displacement of the top of unit 6 can be measured compared

to the topographic surface immediately before the sedimentation of wedge CW1. In this case the

displacement is about 3.9 m in a time window between 23,126 - 22,626 BCE and 12,054 - 11,656

BCE (Fig. 7b). This corresponds to a slip rate of 0.29 - 0.31 mm/yr.

At the Todari roadcut site the total amount of displacement of 1.05 m accumulated after 5,318

- 5,084 BCE (formation of unit 6), provides an average post-5 ka slip rate of 0.14-0.15 mm/yr for this

secondary strand.

At the Anghiari trench site A, the presence of the gravitational sliding surface makes it

difficult to measure a reliable displacement. A minimum of 1.75 m of displacement accumulated from

3,351 -3,096 BCE, estimated by means of the base of the unit 4b (sample TA_C8, assuming a small

amount of motion of the sliding. With this assumption, the calculated slip rate is 0.35 mm/yr.

5.4 Interpretation of secondary features

In the following we discuss a number of points that collectively support an earthquake-

induced origin of the observed secondary features (Fig. 8) under the current extensional stress regime.

Hydrofracturing due to pressurized fluids seems to be the most plausible mechanism for

explaining the pervasive occurrence of fractures and fissures. High fluid pressure would have caused

the opening of fractures, and fluid circulation probably led to the formation of bleaching halos.

Fissures infilled by gray clay from unit 10 indicate that this clay was fluidized, probably due to a

combination of poor lithification and high content of water at elevated pressure. The upward direction

of fluid escape is indicated by the symmetry of flame and injection structures observed at the top of

932   unit 9 (Fig. 8). Moreover, the number of fractures and clay-filled fissures reduce drastically passing

933   from unit 9 to unit 8. This suggests that the clayey paleosol of unit 8 behaved as a cap to upward-

934   directed fluid flow. Different types of soft-sediment deformation in clayey material, generally

935   associated with high hydraulic pressure, were documented in different geologic contexts (e.g., Van

936   Loon, 2009 and references therein), including clay-rich clastic dykes and sills injected due to seismic-

937   induced hydrofracturing and fluidization (e.g., Levi et al., 2006; Montenat et al., 2007).

938   The breccia layer at the top of unit 9 suggests mixing of material from units 9 and 8. Soft-

939   sediment folding of different intensity, in places further deformed into mixed breccia layers, were

940   documented in the Dead See graben (Marco et al., 1996), and are explained with mechanisms of

941   Kelvin–Helmholtz instability due to layer-parallel shear during earthquake shaking (Heifetz et al.,

942   2005). If the shear is unidirectional, such as for gravitational sliding along a sloping surface, folds are

943   asymmetric. In the Villa Sterpeto trench, there are only symmetric flame structures and breccia,

944   suggesting relative shear between the two layers sufficiently intense to produce brecciation and

945   mixing, but not unidirectional. Back and forth displacement due to cyclic shear stress during seismic

946   shaking can be the source of shear energy. The boundary between units 9 and 10 has no evidence of

947   mixing and brecciation. It is very sharp, resembling a shear surface rather than a stratigraphic contact.

948   This could be explained considering relative sliding between two units which are decoupled one from

949   the other along a very weak interface. In other words, seismic shaking would have determined relative

950   displacement, but because of the fluidization of clay within unit 10, the two units were completely

951   decoupled, producing localized shear along the stratigraphic interface. This sharp boundary might

952   appear in conflict with the observation that material from unit 10 intruded into the overlying unit 9,

953   forming clay-filled fissures. Nevertheless, this could be explained if relative shear overprints clay

954   injection, also during the same deformation event when fluidization, clay injection and relative shear

955   are semi-contemporaneous.

53

956   The conjugate fissures observed in map view (Fig. 8d) may suggest, at first glance, a tectonic

957   origin under strike-slip regime. The fissures have significant opening and form a conjugate system,

958   suggesting hybrid extensional shear fractures (e.g., Sibson, 1998) under horizontal σ1 bisecting the

959   acute angle and vertical σ2. Nevertheless, a regional-scale strike-slip stress regime is unlikely for

960   explaining the observed fissures, for three reasons: 1) the main tectonic feature in the trench is a NE-

961   dipping normal fault; 2) AMS results (sec. 4.2.4) are consistent with NE-trending extensional stress;

962   3) fractures and fissures are not localized in a fault zone, but are pervasively distributed within the

963   sedimentary layers, suggesting volumetric deformation. Cyclic shear stress due to seismic shaking

964   might have determined deviatoric stresses within the sheared layer, with local, temporary sub-

965   horizontal σ1 that, in combination with high fluid pressure, would have originated conjugate sets of

966   hybrid extensional shear fractures.

967   Different events of fracturing and fissuring occurred in the site, as testified by thoroughgoing

968   fissures that cut previously formed fissures and breccia layers. This evidence of recurrent events,

969   together with the above considerations on the possible occurrence of shaking-induced shear stress

970   within the sedimentary layers, suggest an earthquake-induced origin for the soft-sediment

971   deformation. The causative earthquakes should have nucleated not very far from the site, as suggested

972   by the dependency of the occurrence of liquefaction features with epicentral distance (e.g., Galli,

973   2000). Possibly, the earthquakes nucleated on the Anghiari normal fault, or on one of the Sansepolcro

974   basin system faults. The earthquakes should be relatively old, when sediments were soft and below

975   the water table, not in the present morphologic setting. Those ancient events occurred before tilting,

976   as the fissures are tilted with the hosting sedimentary layers. Moreover, despite the tilting, the 70°-

977   striking fissures remained subvertical (see stereonet in Fig. 6), indicating that rotation occurred

978   around an axis nearly orthogonal to that direction, which is nearly-parallel to the strike of the Anghiari

979   normal fault. This suggests that tilting is linked to progressive slip on the Anghiari fault.

980   In summary, the secondary features observed in the Villa Sterpeto trench suggest that the site was

affected by i) pervasive soft-sediment deformation under conditions of upward-directed pressurized fluids; ii) differential bedding-parallel shear, with effects at the boundary between units with different rheologies causing mixing or localized shear; iii) superposition of different consecutive deformation events; iv) shaking-induced shear stress due to strong earthquakes on the Sansepolcro basin fault system as the most plausible mechanism for their formation; and v) progressive tilting in the hanging wall of the Anghiari normal fault.

5.5 Seismogenic potential and average extensional rate in the Sansepolcro basin

We calculated the expected maximum magnitude (Mmax) from the mapped fault length using empirical regressions (Wells & Coppersmith, 1994; Leonard, 2014; Galli et al., 2008). From the obtained Mmax we derived the expected average (AD) and maximum displacement (MD). These values, summarized in the tab. 4, refer to two different rupture scenarios: S1) a rupture scenario which involves only the Anghiari fault (from the northern tip of the Micciano section to the southern tip of the Fighille section, total length ~12 km); S2) a rupture scenario which involves the whole Anghiari-Città di Castello main fault (total length ~25.5 km).

On average, the maximum expected magnitude derived from different empirical regressions ranges from 6.2 to 6.7 depending on the scenario. The displacements per event measured in the trenches (≥0.45 m estimated from the thickness of the wedges in the Villa Sterpeto trench and 0.18 to 0.52 m at the Todari roadcut) are comparable with the AD expected for S1 and are smaller, but not very different from the AD expected for S2. The values of displacement estimated from the wedges in the Villa Sterpeto trench (≥0.45 m) and the displacement related to E2_Tod (0.52 m) are also comparable with the expected MD for S1. This is consistent with the observation that the trenches are located in the zone with the greatest morphological expression along the Micciano fault section.

The data collected studying in depth the Anghiari fault can be used to sensibly improve the seismic

hazard assessment in the Sansepolcro basin. In fact, the fault parameters obtained with paleoseismological investigations are fundamental for fault-based seismic hazard assessments, especially where only a few macroseismic information are available from historical catalogs.

A key component in fault-based seismic hazard assessment is the slip rate. Our study provides slip rates based on chronologically constrained Late Quaternary - Holocene offsets. Nevertheless, some doubts arise when comparing the paleoseismological slip rates with the extensional rates from geodetic data. Anderlini et al. (2016) calculated GPS extension rates of ~2 mm/yr along a transect located ~30 km SE of the center of the Sansepolcro basin (across the Ponte Pattoli - Gubbio basins, see Fig. 1). In the Sansepolcro basin the extension is probably less than 2 mm/yr, as extension rate along the Apennines is known to decrease to the NW (Bennet et al., 2012; D'Agostino et al., 2009; D'Agostino, 2014; Anderlini et al., 2016). For example, in D'Agostino (2014) the strain rate across the central Sansepolcro basin (12 to 25 nstrain/yr) is ~40% less than the strain rate across the Ponte Pattoli - Gubbio basins (27 to 35 nstrain/yr). Therefore, the extension rate across the Sansepolcro basin can be estimated to be between 1.5 and 2.0 mm/yr. Even considering the highest calculated paleoseismological slip rate (0.35 mm/yr), the corresponding horizontal extension for an average fault dip of 45° (the Anghiari fault up to 3 km-depth) would be ~0.25 mm/yr, which is ~⅙ of the minimum estimated GPS extension. Assuming that a comparable amount of extension is accommodated by the Sansepolcro antithetic fault, there is still ~1 mm/yr of GPS extension to be explained. This suggests one or probably a combination of the following:

- a large part of the geodetic extension is accommodated by distributed deformation between major faults, not detectable by classical geologic investigations;

- we underestimate the slip rate as we possibly missed some secondary splaying faults and/or missed the sites of maximum displacement on the Anghiari fault;

- other splays of the ATF, such as the Sovara synthetic splay, accommodate part of the extension.

A work aimed at estimating the slip rate of the fault system systematically and at a wider scale, also using geologic and geomorphic markers covering a time range wider than that constrained in this work can help a better understanding of the extensional rate of the basin during its recent evolution.

Rupture Scenario	Length (km)	M max					AD (m)			MD (m)		W (km)		
		WC94 N	WC94 all	L14 DS	G08	Average	WC94 N	WC94 all	L14 DS	WC94 N	WC94 all	WC94 N	WC94 all	L14 DS
Anghiari Fault	12	6.28	6.33	6.27	6.13	6.25	0.32	0.37	0.5	0.49	0.54	11.47	10.38	8.62
Anghiari-Città di Castello main fault	25.5	6.72	6.71	6.79	6.63	6.71	0.60	0.68	0.91	1.20	1.11	16.25	13.73	14.17

Tab.4. Expected value of max magnitude (Mmax), average displacement (AD) and maximum displacement (MD) for two rupture scenarios involving the Anghiari fault or the whole Anghiari-Città di Castello main fault, according to the empirical relations by Wells and Coppersmith (1994) normal fault and all kinematics (WC94 N and WC94 all), Leonard 2014 deep slip (L14 DS) and Galli et al 2008 (G08).

5.6 Potential implications for activity and seismogenic behavior of a continental LANF

The evidence of surface faulting earthquakes along the Anghiari fault has potential implications in our understanding of the present activity and the seismogenic behavior of LANFs. The Anghiari fault is considered as the easternmost active synthetic splay of the ATF LANF by some authors (e.g., Barchi et al., 1998a; Brozzetti et al., 2009; Pucci et al., 2014; Bonini et al., 2016). The present activity of the ATF LANF was inferred mostly on the basis of microseismicity recorded SE of the Upper Tiber River valley, combined with seismic reflection data (Chiaraluce et al., 2007). The creeping versus seismogenic behavior, and the link with the Anghiari fault are the two major issues to address about the ATF LANF.

Although the frictional fault reactivation theory predicts that slip on LANF is extremely unlikely (Collettini, 2011), the ATF capacity to source moderate to strong earthquakes (i.e., Mw ≥ 6) has been inferred from regional seismotectonic considerations. Brozzetti et al. (2009) claimed that the southern sector of the UTV (SSE of Città di Castello) is characterized by creeping, as suggested by the intense microseismicity and the lack of historical strong earthquakes, while the northern sector

(the Sansepolcro basin) is characterized by a seismogenic behavior, as suggested by the low microseismicity and the occurrence of strong historical earthquakes. High-resolution seismologic and geodetic data documented mixed-mode (seismic and aseismic) slip behavior along the ATF (Anderlini et al., 2016; Valoroso et al., 2017) and swarm-like events on its high-angle splay faults (Gualandi et al. 2017). Particularly, according to geodetic data, Anderlini et al. (2016) argue that the ATF LANF shows both locked and creeping patches, in agreement with the possibility to nucleate strong earthquakes in the Sansepolcro basin.

To address the issue of the link with the Anghiari fault, first we have to reconcile the ground surface observations and the deep model of this low-angle fault. At the surface, the Anghiari fault does not dip at low-angle. The dip is 48-60° in the Villa Sterpeto trench, from 40° to 74° in the Podere Todari road cut, and 46° and 70-80° (two synthetic splays) in the Anghiari trench (site A). In high-resolution shallow seismic reflection profiles, the fault dips ~53° up to depths of ~40 m (Micciano section, Villa Sterpeto site, Fig. 5) and ~51° up to depths of ~300 m (Anghiari-Motina section, Delle Donne et al., 2007). There are two possible interpretations about the link between the ATF LANF and the Anghiari fault:

      1) the Anghiari fault dips steeply in the near-surface and becomes progressively less inclined at depth, soling into the ATF LANF at depths of 3-4 km as indicated in section A-A' of Fig. 1 (from Brozzetti et al., 2009);

      2) the Anghiari fault dips steeply across the entire brittle crust and offset the ATF LANF.

      The first option follows the classical model of LANF, and the second one is not yet supported by data. Such information would require additional investigations. There is no high-resolution geophysical data that can image with sufficient detail the fault intersection in the 3-5 km-depth interval, and there is no detailed aftershock data of earthquakes sufficiently large to illuminate an appreciable size of the Anghiari fault.

Field observations do not allow us to discriminate between these two hypotheses. The sedimentary succession in the hanging wall of the Anghiari fault is tilted against the fault and the tilting decreases from older to younger sediments (up to 30° the CTA beds; 5-15° the MTC beds, <5° the bottom of Late Pleistocene colluvium; Figs. 3, 6). Moreover, the CTA beds are tilted in the footwall of the Anghiari fault (Fig. S1, S3), suggesting that the Anghiari fault cuts through an already tilted succession in the hanging wall of the Sovara parallel fault. This evidence can suggest progressive hanging wall rollover due to listric faulting (e.g., Dula, 1991) during syn-tectonic sedimentation with an extensional model of imbricated listric normal faults rejuvenating in the direction of extension and soling into the same detachment level (Wernicke & Burchfiel, 1982). On the other hand, this would also be expected in a domino-style tilt block model of faulting (Wernicke & Burchfiel, 1982; Leeder & Gawthorpe, 1987) also observed in seismic reflection datasets (Jackson et al., 2017). Only high-resolution geophysical data can solve this uncertainty.

If the Anghiari fault is detaching on the ATF LANF at depths of ~3.5 km as in section A-A' of Fig. 1, its down-dip width is ~5 km (average dip of 45°). To generate a M≈6.2 earthquake, a rupture width (W) of about 9-11 km is expected (Wells & Coppersmith, 1994; Leonard, 2014). This implies that at least 4-5 km of the ruptured W should be on the ~25°-dipping ATF LANF (up to depths of 5-6 km). For a M≈6.7 earthquake, the expected W is about 13-16 km. Therefore, the expected down-dip ruptured portion of the LANF is about 8-11 km, which is close to the entire 25°-dipping ramp of the LANF in section A-A' of Fig. 1 (up to depths of ~7 km).

In synthesis, field data could support an active, seismogenic behavior of the ATF LANF, especially of the youngest and easternmost NE-dipping Anghiari splay and its down-dip continuation into the low-angle (dip≤25°) detachment. But high-resolution geophysical data in the 3-5 km-depth range appears essential for solving this issue.

Karlsson et al. (2021) came to similar conclusions by studying the case of the Cañada David detachment (Baja California-Mexico). They suggest that this severely misoriented LANF is capable

of nucleating strong surface faulting earthquakes, as well as other well-oriented faults in the system. As a possible mechanical explanation, they propose the "keystone fault hypothesis" formulated by Fletcher et al. (2016). The severely misoriented LANF would act as a keystone fault, able to regulate slip of other faults in the system. During interseismic loading, optimally-oriented faults would bleed off the excess shear stress in small slip events and creep determining continuous stress built-up on the keystone LANF until its seismogenic failure together with other high-angle faults in its hanging wall.

6. Conclusions

We revealed for the first time the slip history of the Anghiari fault, a 12 km-long normal fault considered in the literature to be a synthetic splay of a low-angle normal fault (Altotiberina LANF). The Anghiari fault displaces Lower-Middle Pleistocene to Holocene deposits and is capable of faulting the ground surface during strong earthquakes. The magnetic susceptibility anisotropy analysis indicates a continuously active extensional stress field. Pervasive soft-sediment deformation within the tilted Pleistocene deposits suggests repeating severe ground shaking due to strong earthquakes on the Sansepolcro basin normal fault system, and progressive tilting in the hanging wall of the Anghiari normal fault.

The most recent surface faulting earthquake (MRE_Tod) is compatible with the poorly-constrained 1458 earthquake, which damaged the Città di Castello and Sansepolcro towns within the Sansepolcro basin.

According to empirical regressions, the expected maximum magnitude is on average between 6.2 and 6.7, depending on the rupture scenario.

The paleoseismological slip rate of the Anghiari fault varies between 0.14 (over the last 7 ka) and 0.35 mm/yr (over the last 5 ka), depending on the considered fault section, with a mean value >0.2 mm/yr over the last 25 ka, measured in the Villa Sterpeto trench.

The mean recurrence interval ranges from about 2500 and 3200 years, depending on the different earthquakes age hypotheses considered. The coefficient of variation of the recurrence time is between about 0.6 and 0.9, suggesting a non-periodic behavior.

If the Anghiari fault is actually the surface expression of a LANF that steepens progressively within the shallowest 3-5 km of depths and breaches the ground, our work can be among the few ones worldwide documenting the geological evidence of an active and seismogenic LANF, suggesting that earthquakes on LANFs can be less rare than previously thought. Even though only a large seismogenic rupture can solve the issue unambiguously, very high-resolution geophysics in the 3-5 km-depth interval can help to prove the connection between the paleoseismological evidence of earthquake surface faulting and the deep low-angle plane, which is challenging for future research.

Additional Supporting Information

Report of Radiocarbon Dating Analysis

Introduction

The supporting information include additional information regarding the geophysical acquisition and processing (Text S1); additional information about the anisotropy of magnetic susceptibility methodology (Text S2); the detailed description of the stratigraphy of the trenches (Text S3); the orthophoto-mosaic of each trench (Figure S1 to S4); the results of the analysis of the anisotropy of magnetic susceptibility (Fig. S5 and Tab. S1); the results of the radiocarbon datings and the calibration of uncalibrated ages provided by the Laboratory Plateforme Nationale LMC14 (France) (Fig. S6).

Text S1.

Geophysical Acquisition and processing:

Text S1.

Geophysical Acquisition and processing:

Seismic Reflection (SR): A sledgehammer source of 8 kg was used to produce a vertical impact on a metallic plate located on the ground, together with a trigger geophone, and shooting every 2 m (123 shots in total). The acquisition was accomplished using a roll-along scheme, using a channel overlap of 24 and achieving 336 CDP with a max fold number of 42.Upon setting up the geometry, the conventional processing scheme included a data quality control (QC) of the shot gathers and a first break picking across 8860 traces, using the Generalised Reciprocal Method (GRM, Palmer, 1980), and inverted via software Rayfract v. 3.34, obtaining a velocity model with the lowest Root-Mean Square (RMS) value after 19 iterations. Seismic reflections were processed using the commercial software RadExPro to obtain a stack seismic profile with improved S/N ratio (Yilmaz, 2001), achieved after applying these steps: Automatic Gain Control, Top Mute, Spectral Shaping, Bandpass and F-K filters, Spiking Deconvolution, Statics, Velocity Analysis, Normal MoveOut Correction and Stacking, FX-Deconvolution and Depth Conversion (using a smoothed RMS velocity model).

Ground Penetrating Radar (GPR): A 100 ns time window with 1024 samples/trace, and a trace spacing of 0.02 m was used. The processing flow used is based on the schemes already reported in Ercoli et al. (2014, 2015), thus encompassing conventional steps (Jol, 2009) such as trace editing/killing and coordinate/elevation correction, time-zero alignment and correction, dewow and bandpass filtering, amplitude recovery, horizontal smoothing filter, topographic correction and time-to depth conversion (Vem = 0.01 m/ns-1).

Electrical Resistivity Tomography (ERT): The survey has been carried out using 56 one-meter spaced electrodes with both the Wenner-Schlumberger and Dipole-Dipole configuration., for an investigation depth of about 8-10 m.
Data processing was carried out using the ZondRes2D software.

Text S2.

Anisotropy of Magnetic susceptibility

The AMS is a second order tensor ellipsoid characterized by the orientation and magnitude of its principal axes (kmax, kint and kmin, being the maximum, intermediate, and minimum susceptibility axes, respectively, Tarling & Hrouda 1993). The relative magnitude of its axes defines the shape of the AMS ellipsoid: (1) isotropic (kmax=kint=kmin) when crystals have no preferred orientation or when strongly magnetic grains have a random distribution; (2) oblate (kmax≈kint >> kmin) when crystal alignment defines a foliation plane; (3) prolate (kmax>>kint ≈ kmin) when crystal alignment defines a lineation plane; or (4) triaxial (kmin < kint < kmax). The strength of anisotropy can be described by the corrected anisotropy degree (PJ; Jelınek, 1978), where PJ = 1.0 indicates an isotropic fabric and, for example, PJ = 1.05 indicates 5% anisotropy. The shape of the ellipsoid is described by the shape parameter (T), where −1.0 < T < 1.0 with positive/negative values of T indicate oblate/prolate fabrics, respectively (Jelınek, 1978). AMS can be used to distinguish an undeformed sedimentary rock (typically with a weakly oblate fabric) from a weakly to strongly deformed rock (a weakly or strongly prolate or triaxial ellipsoid; see reviews by Hrouda, 1982; Borradaile, 1988; Tarling & Hrouda, 1993; Borradaile & Henry, 1997; Borradaile & Jackson, 2004).

Text S3

Stratigraphy of the Villa Sterpeto trench

The stratigraphy of the Villa Sterpeto trench is described in detail below, starting from the oldest unit.

Unit 11 is made of whitish, grain-supported, polygenic dense conglomerate, with light brown sandy matrix, dominant carbonate and few sandstone and quartz clasts. Sub-rounded pebbles and cobbles prevail but there are also rare boulders. The clasts are imbricated showing a westward flow provenance and the layers apparently dip from 5° to 17° toward west. This unit represents the most prominent relief cropping out only in the footwall of the fault zone.

Unit 10 is made of blue-gray stiff clay, with ochraceous mottling. The upper part is characterized by the presence of calcium carbonate concretions. This unit is the oldest found in the fault hanging wall. The boundary with the overlaying unit 9 is sharp and

dips ~12° westward.

Unit 9 consists of dark yellowish-orange, very dense sand with rare arenaceous pebbles and interbedded layers of black quartz clasts. This unit is featured by several layer-parallel and layer-perpendicular fissures, infilled by gray clay from unit 10. The transition to the upper unit 8 is characterized by breccia horizons and flame structures described in the main text.

Unit 8 is a deeply pedogenised unit that can be divided into three sub-units, from bottom to the top: 8c) very dusky red to blackish red clay without manganese coating; 8b) dark brown to moderate reddish-brown clay with few manganese coating; 8a) dark reddish brown to dusky brown clay with abundant manganese coating. All the three subunits are crossed by layer-perpendicular fractures. This unit is unconformably overlayed by units 1 and 2 and interfingers with unit 7 westward. The maximum thickness of unit 8 is ~6 m. Unit 7 consists of dark yellowish orange to dark brown, very gravelly, very stiff clay with abundant manganese coatings. The clasts are sub-angular pebbles and cobbles and rare boulders, mainly made of altered sandstones and rare black clasts. This unit is featured by irregularly shaped veins filled by gray to green clay. The maximum visible thickness is ~1.5 m.

Unit 6 is a dusky brown paedogenetic horizon (paleosol) made of sandy clay with polygenic, sub-angular pebbles and cobbles and manganese coatings and nodules. The boundary with the underlying unit 7 is marked by a 5 cm-thick clayey layer. The age of unit 6 is constrained by the sample VS_C01 (23,126 – 22,626 BCE, Fig 7, Tab. 1). Unit 5 is a light to moderate brown sandy clay with sparse polygenic, sub-angular pebbles and cobbles. This unit overlays unit 6 and is overlayed by unit 3. The age of unit 5 is constrained by four samples collected within this unit for radiocarbon dating (bulk organic fraction, Tab. 1). From the top to the bottom the radiocarbon dating gave

ages of 12,054 – 11,656 BCE (VS_C12); 13,677 – 13,351 BCE (VS_C13); 15,863 – 15,198 BCE (VS_C03) and 14,106 – 13,717 BCE (VS_C02). The ages are all coherent with each other, except for VS_C02 and VS_C03 which are inverted. Unit 4 is a colluvial deposit formed by dark yellowish-brown, polygenic, grain-supported, dense gravel with sandy matrix sourced from unit 11. This unit is directly faulted against unit 11 and inter-fingers with unit 5.

Unit 3 is a reddish-brown paleosol with sub-angular blocky structure, deriving from paedogenetic alteration of the underlying unit 5. The age of unit 3 is constrained by the sample VS_C06bis (4,551 – 4,363 BCE; Fig. 7).

Unit 2 is a young colluvium with pottery shards, divided into two sub-units: 2a) moderate brown clayey sand with horizons of polygenic pebbles and cobbles; 2b) moderate brown gravel with polygenic pebbles and cobbles.

Unit 1 is an anthropogenic deposit made of heterometric gravel from unit 11, with light brown clayey sand matrix. It contains pottery shards and modern anthropogenic backfill.

Stratigraphy of the Todari site

The stratigraphy of the Todari site is described in detail below, starting from the oldest unit.

Unit 7 is made of very dense ochraceous fine sand with strata and lenses of dense polygenic, grain-supported gravel with sub-rounded calcareous and subordinately sandstone pebbles and rare cobbles. In the footwall of the main fault, unit 7 is directly overlayed by the present-day soil (unit 1a). The uppermost part of unit 7 is the eluvium of the unit, consisting of light olive brown sandy clay.

In the hanging wall of the main fault, unit 7 is located at the bottom of the outcrop and it is overlayed by unit 6.

Unit 6 is composed of grayish olive to dark yellowish brown very stiff clay with polyhedral structure and sparse calcium carbonate nodules. This unit is a clayey paleosol developed on top of unit 7. It crops out between the main fault and the antithetic fault. According to the sample Tod_C01bis, the age of this unit is between 5,318 and 5,084 BCE (Tab. 1.).

Unit 5 is made of moderate olive brown to grayish olive, moderately firm, thinly laminated clay, and it crops out only in the hanging wall of the main fault. The bottom of this unit is the contact with unit 6, while on top it is covered by units 4 and 1. The unit 5 has an age between the samples Tod_C02 (3,468 - 3,561 BCE) and Tod_C03 (928 - 810 BCE) (Tab. 1).

Unit 4 is made of moderate brown to dark yellowish-brown, soft to firm clay with red and gray mottling and sparse millimetric to centimetric calcium carbonate nodules. This unit constitutes a colluvial wedge delimited by unit 5 at the bottom, units 3 and 1 at the top and the filled fissure (FF) to the west. Sample Tod_C06, collected close to the base of the unit, has an age of 668 - 874 CE.

Unit FF is the infill of a large fissure topped by unit 3. This unit is mainly made of sand with sparse sub-rounded and sub-centimetric calcareous clasts. Sample Tod_C05, collected within the unit, has an age of 1,408 - 1,460 BCE.

Unit 3 is a colluvial wedge bounded by units 1 and 2 at the top, unit 4 at the bottom, and the filled fissure and unit 7 to the west. It consists of dusky yellow to light olive brown, slightly clayey sand with sparse fine gravel and interbedded layers of calcareous sub-rounded and flat small pebbles iso-oriented as the wedge. There are no dated

samples in this unit, but it is younger than unit FF and older than the unit 2. Its age is, therefore, between 1,408 - 1,460 CE (Tod_C05) and 1,495 - 1,656 CE (Tod_C04).

Unit 2 is a grayish brown to dusky brown soft clayey colluvial wedge with calcareous sub-rounded and flattened medium pebbles and granules, iso-oriented as the wedge. This unit is interfingered with the unit 1 and is bounded at the bottom by unit 3 and at the top by unit 1. Sample Tod_C04, collected within unit 2, has an age of 1,495 - 1,656 CE.

Unit 1 is divided into two sub-units: 1a) modern soil made of grayish brown to dark yellowish-brown clay and sandy clay with sparse calcareous pebbles and calcium carbonates nodules; 1b) moderate yellowish brown soft sandy clay with sparse fine gravel and rare pebbles. The base of 1b is marked by a layer of grayish brown to yellowish gray sand. Subunit 1a is the youngest, while subunit 1b interfingers with unit 2, and therefore should have the same age.

Stratigraphy of the Anghiari trench site A

The stratigraphy of the Anghiari trench site A is illustrated in detail below, starting from the oldest unit.

Unit 11 is made of plastic, firm gray-bluish clay, passing upward to stiff and fractured, orange to yellowish, silt and sandy-silt. The unit possibly belongs to the FIG synthem.

Unit 10 is made of grain-supported gravel with a sandy matrix. The clasts are mainly made of calcareous, sub-rounded pebbles and cobbles. This unit has an erosive base and belongs to the CTA synthem.

Unit 9 corresponds to the remnant of an alluvial deposit and is made of grain-supported gravel with a light brown sandy matrix. The clasts are mainly calcareous, sub-rounded pebbles and cobbles. This unit has an erosive base and covers a pedogenised surface.

Unit 8 is a colluvium made of dark yellow to greenish massive, fractured, firm and moderately plastic slightly sandy clay.

Unit 7 is a colluvium made of olive gray massive, fractured, stiff to firm and moderately plastic silty and gravelly clay. The clasts are mainly calcareous large pebbles and cobbles.

Unit 6 is a colluvium made of stiff and plastic grayish slightly silty clay with orange to yellow mottling. It contains rare sandstone sub-angular to sub-rounded granules and cobbles and frequent charcoal. The base is characterized by a discontinuous gravelly clay horizon.

Unit 5 is a lacustrine-palustrine unit made of grayish firm and plastic slightly sandy clay. It contains rare sub-angular to sub-rounded pebbles and cobbles of sandstone. Based on stratigraphic considerations (see below), we interpret the base of this unit (between fault zones 3 and 1; Fig. 10 of the main text), as an abnormal contact, probably a gravitational slide along the former slope. Unit 4b is an olive gray pedogenized colluvial deposit made of fractured, firm, and moderately plastic slightly sandy clay, containing fine gravel and charcoal. It is darker in the upper part. This unit crops out both in the hanging wall and in the footwall of the main fault zone. The age of this unit has been constrained thanks to radiocarbon dating of charcoal. The two samples, collected in the footwall (sample TA_C3) and in the hanging wall (sample TA_C8) of the main fault zone, have ages of 3,076 - 2,899 BCE and 3,351 - 3,096 BCE, respectively.

Unit 4a is a colluvial deposit made of matrix-supported gravel and brown to green-yellowish firm, moderately plastic sandy-silty clay. The clasts are mainly calcareous, sub-rounded to sub-angular granules to large pebbles. Contains pottery shards (sample

TA_C4p) of the IV-VI century CE (ages of pottery shards are from archaeological evaluation by O. Menozzi, Univ. of Chieti-Pescara, pers. comm.).

Unit 3b is a colluvial deposit made of matrix supported gravel with brown-yellowish fine sand and silty matrix. The clasts are mainly calcareous large pebbles and cobbles.

Unit 3a is a colluvial deposit made of brown-yellowish clay and silt with rare granules and coarse sand. It contains charcoal and pottery shards (sample TA_C9p) of the V-VII century CE (ages of pottery shards are from archaeological evaluation by O. Menozzi, Univ. of Chieti-Pescara, pers. comm.). The radiocarbon age of the sample TA_C6 is between 571 and 651 CE, in agreement with the age of the archeological findings.

Unit 2 is a colluvial slope-derived deposit made of matrix-supported gravel with a brown yellowish slightly clayey sandy and silty matrix. The clasts are mainly sub-rounded pebbles and cobbles. It contains reworked pottery shards (samples TA_7p, TA_10p, TA_14p) of the VII-XIV century CE (ages of pottery shards are from archaeological evaluation by O. Menozzi, Univ. of Chieti-Pescara, pers. comm.).

Unit 1 is a modern anthropogenic backfill with plastic remains and very young pottery fragments.

1: Anthropic backfill; 2: Olive-brown firm and moderately plastic slightly gravelly clay, with black clasts and manganese patinas. Contains gravelly clay with orange to yellowish mottling and sub angular to sub rounded pebbles; 3: Yellow to greenish firm and highly plastic clay with sparse sandstone pebbles and cobbles and orange to yellow mottling.4: yellow-brown clayey gravel made of sub angular and altered sandstone pebbles and cobbles. Black and quartz clasts are also present. The base is marked by a 20 cm thick gray to yellowish layer of clayey to gravelly dense silt. The top corresponds to a gravitational sliding surface filled with gray clay;5: grain supported gravel with a brown to yellowish sandy clay matrix. The gravel is made of subrounded pebbles and rare cobbles. Black patinas are abundant.

Table S1. Anisotropy of the magnetic susceptibility (AMS) results for the Anghiari section. Site indicates the site (block) name, N is the number of samples measured from each site; k is the mean susceptibility; the normalized principal susceptibilities are the second order tensor axis, where kmax is the maximum axis of susceptibility, kint is the intermediate, and the kmin is the minimum axis. The principal axis orientation of each axis are also reported as azimuth and dip. The Jelinek parameters indicate the grade of anisotropy, Pj, and the shape, T.

Addictional Supporting Information. Complete reports of the radiocarbon dating analyses by Beta Analytic Testing Laboratory and Laboratory Plateforme Nationale LMC14 (France).
The uncalibrated ages of the samples tested by the Laboratory Plateforme Nationale LMC14 have been calibrated by us using OxCal v4.4 (Bronk Ramsey, 1995 and 2009) and the IntCal20 atmospheric calibration model (Reimer et al, 2020), as reported in the last page of this document.

Quality Assurance Report

This report provides the results of reference materials used to validate radiocarbon analyses prior to reporting. Known-value reference materials were analyzed quasi-simultaneously with the unknowns. Results are reported as expected values vs measured values. Reported values are calculated relative to NISTSRM-1990C and corrected for isotopic fractionation. Results are reported using the direct analytical measure percent modern carbon (pMC) with one relative standard deviation. Agreement between expected and measured values is taken as being within 2 sigma agreement (error x 2) to account for total laboratory error.

Report Date: January 03, 2022
Submitter: Prof. Paolo Boncio

QA MEASUREMENTS

Reference 1

Expected Value: 0.42 +/- 0.04 pMC

Measured Value: 0.42 +/- 0.03 pMC

Agreement: Accepted

Reference 2

Expected Value: 129.41 +/- 0.06 pMC

Measured Value: 129.43 +/- 0.35 pMC

Agreement: Accepted

Reference 3

Expected Value: 96.69 +/- 0.50 pMC

Measured Value: 96.63 +/- 0.28 pMC

Agreement: Accepted

COMMENT: All measurements passed acceptance tests.

Calibration of the uncalibrated ages of the samplse analysed by the Laboratory
Plateforme Nationale LMC14 (France) using OxCal v4.4 (Bronk Ramsey 2021) and the IntCal20
atmospheric calibration model (Reimer et al, 2020)

OxCal v4.4 Bronk Ramsey (2021); r:5; Atmospheric data from Reimer et al (2020)
VS_C02 R_Date(13210,60)
95.4% probability
14106 (95.4%) 13717calBC

OxCal v4.4 Bronk Ramsey (2021); r:5; Atmospheric data from Reimer et al (2020)
VS_C03 R_Date(14330,70)
95.4% probability
15863 (91.2%) 15321calBC
15286 (4.3%) 15198calBC

OxCal v4.4 Bronk Ramsey (2021); r:5; Atmospheric data from Reimer et al (2020)
VS_C06bis R_Date(5650,35)
95.4% probability
4551 (78.5%) 4436calBC
4430 (16.9%) 4363calBC

OxCal v4.4 Bronk Ramsey (2021); r:5; Atmospheric data from Reimer et al (2020)
VS_C07 R_Date(1990,30)
95.4% probability
46calBC (88.2%) 85calAD
95 (7.3%) 117calAD

OxCal v4.4 Bronk Ramsey (2021); r:5; Atmospheric data from Reimer et al (2020)
VS_C08 R_Date(5330,30)
95.4% probability
4315 (3.1%) 4300calBC
4252 (45.4%) 4151calBC
4145 (47.0%) 4050calBC

Name	Conventional Age (BP)	Calibrated Age (BC/AD)
