Key Points:

- The origin and environmental implications of Al-poor X-ray amorphous material in Gale crater and elsewhere on Mars remain unclear.

- We describe Mars-relevent X-ray amorphous material chemical heterogeneity in ultramafic soils in Mediterranean and subarctic climates.

- X-ray amorphous material forming under subarctic conditions is more chemically similar to Martian X-ray amorphous material.

Abstract

X-ray amorphous material that is variably Mg/Fe/Si-rich and Al-poor and that likely contains secondary alteration products is prevalent in Gale crater sediments and rocks (15-73 wt.%). However, the structure and origin of these materials and their implications for past environmental conditions remain unknown. In this study, we use transmission electron microscopy and synchrotron microprobe analyses to examine Mg/Fe/Si-rich and Al-poor ultramafic soils from the warm mediterranean climate Klamath Mountains of California and cold subarctic climate Tablelands of Newfoundland, Canada to help interpret environmental conditions during the formation of chemically similar X-ray amorphous material in Gale crater, Mars. Primary glass is absent from the Klamath Mountains and Tablelands materials; secondary X-ray amorphous material includes globular amorphous silica and chemically heterogeneous nanospherical amorphous material and nanocrystalline phases. Globular amorphous silica is only present in soils that undergo extensive periods of cyclic freezing. Fe-containing X-ray amorphous material from the subarctic Tablelands is significantly richer in Mg and Si than X-ray amorphous material from the warmer Klamath Mountains. Fe-rich nanocrystallites contain more Mg and Si in the subarctic Tablelands but are more highly Fe-enriched in the warmer Klamath Mountains. Potential secondary nanocrystalline phyllosilicates are only observed in the warmest examined soil in the Klamath Mountains. These characteristics – the presence or absence of amorphous silica, the chemical composition of X-ray amorphous material, the abundance and composition of Fe-rich nanocrystallites, and the presence or absence of secondary phyllosilicates - provide helpful identifiers to interpret past environmental conditions during the formation of X-ray amorphous material on Mars.

Plain Language Summary

The kinds of minerals and materials within martian rocks and loose sediments can provide clues to the conditions that were present during their alteration or production. X-ray amorphous material, material that lacks crystal structure as well as nanocrystallites less than roughly 100 nm in diameter, has been found in abundance within sediments and rocks at Gale crater on Mars. Beyond chemical data and abundance estimates, we do not know much about what this material is the implications of its presence for past environmental conditions. Therefore, we investigated the chemical and structural properties of chemically similar amorphous material in terrestrial soils developing under warm mediterannean and cold subarctic climatic conditions. Colder conditions correlate with greater magnesium and silica content and the presence of pure amorphous silica. Wamer conditions are associated with a lack of amorphous silica, lower magnesium and silica content within Fe-containing X-ray amorphous material, the formation of purely iron containing nanocrystallites, and the presence of nanocrystalline clay minerals. The chemical content of X-ray amorphous material forming under subarctic conditions is statistically more similar to that found at Gale crater. These results are consistent with the Gale crater X-ray amorphous material forming under generally cold and icy conditions.

1 Introduction

Analyses of X-ray diffraction data from the CheMin instrument on the Mars Science Laboratory rover have documented abundant (15-73 wt.%) X-ray amorphous material, likely encompassing amorphous material, short-range order phases, and nanocrystallites less than roughly 100 nm in diameter (Klug & Alexander, 1974; Smith & Horgan, 2021), in all ancient fluvial-lacustrine and aeolian rocks and modern aeolian sediments analyzed to date at Gale crater, Mars (Rampe et al., 2020; Thorpe et al., 2022). Mass balance calculations using CheMin mineral abundances and geochemical data from the Alpha Particle X-ray Spectrometer (APXS) instrument suggest that this X-ray amorphous material is variably Fe- (3.0 – 43.1 wt.% FeO_T) and Si-rich (3.6 – 75.9 wt.% SiO_2), Al-poor ($\leq$10.46 wt.% Al_2O_3), sometimes Mg-rich (0.0 – 25.23 wt.% MgO) (Rampe et al., 2020; Smith et al., 2021; Thorpe et al., 2022), and contains secondary weathering products based on abundant volatile content (H_2O, CO_2, SO_2) measured by the Sample Analysis on Mars (SAM) instrument (Millan et al., 2022; Rampe et al., 2020). X-ray amorphous material can form through a variety of processes including volcanism (Nakagawa & Ohba, 2003), impact melting (Dressler & Reimold, 2001), anhydrous oxidation (Salvatore et al., 2019), aqueous alteration (Hiradate & Wada, 2005; Tutolo et al., 2019), and precipitation from aqueous solution (Ralston et al., 2021). While the formation mechanisms of the X-ray amorphous material in Gale crater remain poorly understood, inversely proportional FeO_T and SiO_2, SiO_2 that is directly proportional to total X-ray amorphous wt.% abundance, and potential primary glass contributions of ~0.1-57 wt.% are consistent with a substantial proportion of the Gale crater X-ray amorphous material being composed of aqueous alteration products (Smith et al. 2021).

Due to the typically Mg/Fe/Si-rich and Al-poor composition of serpentinized ultramafic bedrock, weathering of serpentinites produces secondary materials enriched in Mg/Fe/Si and depleted in Al (Baumeister et al., 2015; Caillaud et al., 2004; Rabenhorst et al., 1982). Previous work has utilized serpentinite-derived soils, sediments, and bedrock as analog settings for examining potential martian geochemical processes including the effects of climate and chemical mobility on the production of secondary clay minerals and Fe-oxides (Gaudin et al., 2011), the production of short-range order phyllosilicates during serpentinization processes (Tutolo et al., 2019), the potential for serpentinization processes to have abiotically contributed hydrogen (Greenberger et al., 2015) and methane (Szponar et al., 2013) to the early martian atmosphere, and the potential for serpentinization to produce clay and carbonate mineral assemblages similar to those found in Jezero crater (Grosch et al., 2021). Serpentinized minerals (serpentine and talc) have also been directly detected within Jezero crater where the Perseverance rover is currently caching samples for return to Earth (Farley et al., 2022; Liu et al., 2022), and the serpentine polymorph greenalite is potentially present in the sedimentary rocks at Glen Torridon in Gale crater (Thorpe et al., 2022). Serpentine soils therefore provide a useful Mg/Fe/Si-rich and Al-poor chemical environment for studying the influence of climatic variation on the development of Fe/Si-rich, sometimes Mg-rich, and Al-poor X-ray amorphous aqueous alteration products like those found in Gale crater and potentially elsewhere on Mars.

The prevalence of juvenile and X-ray amorphous secondary products on Mars has been proposed to indicate generally cold and icy, sometimes wet, conditions during formation (Rampe et al., 2022; Thorpe et al., 2021; Tosca & Knoll, 2009). Amorphous aluminosilicates such as allophane are typically thought to be transient phases that alter to more crystalline minerals over

111 time (Harsh et al., 2002; Wada, 1989). Previous work examining the formation and longevity of
112 amorphous and short-range order aluminosilicates such as allophane in terrestrial field
113 environments suggests that kinetically limiting conditions such as colder temperatures (Rampe et
114 al., 2022; Rasmussen et al., 2010; Yesavage et al., 2015) or episodic high-intensity but short-
115 duration aqueous alteration under generally highly arid conditions (Ziegler et al., 2003) can
116 promote the formation and persistence of amorphous aluminosilicates. However, to our
117 knowledge, no work to date has similarly examined the effects of temperature over time on the
118 chemical heterogeneity of Mg/Fe/Si-rich but Al-poor X-ray amorphous material in terrestrial
119 ultramafic soils that are chemically relevant to similarly Al-poor X-ray amorphous material on
120 Mars.

121 Therefore, in this work soils from a suite of Mg/Fe/Si-rich and Al-poor ultramafic soils
122 developing under the mediterranean climate of the Klamath Mountains of northern California
123 and the subarctic climate of the Tablelands of Newfoundland, Canada were examined as analogs
124 to the Fe/Si-rich, occasionally Mg-rich, and Al-poor X-ray amorphous material found in Gale
125 crater, Mars. Bulk soil grain mounts were analyzed via synchrotron microprobe
126 microfluorescence (μXRF), microdiffraction (μXRD), and X-ray absorption fine structure
127 (XAFS) techniques. Results indicate that the presence of amorphous silica, greater Mg- and Si-
128 incorporation within X-ray amorphous material coupled with a more limited formation of more
129 purely Fe-containing nanocrystallites, and the absence of secondary phyllosilicates are consistent
130 with colder conditions. By contrast the absence of amorphous silica, the formation of more
131 purely Fe-containing X-ray amorphous material including Fe-(oxyhydr)oxide nanocrystallites,
132 and the presence of secondary phyllosilicates are consistent with warmer conditions. These
133 indicators may therefore be useful in interpreting aqueously altered materials on Mars and in
134 samples returned from Mars.

135 **2 Materials and Methods**

136 *2.1 Field Sites and Soil Material*

137 Ultramafic soil samples were collected from two sites dubbed Eunice Bluff and String
138 Bean Creek in the Klamath Mountains in August 2018 and from two sites dubbed Devil's
139 Punchbowl and Trout River Gulch in the Tablelands of Gros Morne National Park on
140 Newfoundland, Canada in October 2018 (Figure 1, Table S1). Temperature and precipitation
141 averages from the Environment Canada continuous weather monitoring station in Cow Head, NL
142 most proximal to the Tablelands indicate that the Tablelands have a mean annual temperature of
143 <3.9 ⁰C and precipitation of ~120.4 cm/year water equivalents, with ~178 days with below
144 freezing temperatures (Environment Canada, 2010). NOAA SNOTEL continuous climate
145 monitoring stations at Weaverville, CA (elevation: ~610 m) and Sawyers Bar, CA (elevation:
146 ~659 m) indicate that low- to mid-elevation regions of the Klamath Mountains as at String Bean
147 Creek (~1,120 m) on average possess a mean annual temperature of ~12.8 ⁰C and water
148 equivalent precipitation of ~101.2-117.6 cm/year with ~93 days per year experiencing below
149 freezing temperatures though mean daily temperatures remain above freezing year-round
150 (Arguez et al., 2010; Skinner et al., 2006). Climate data from a weather station on Red Rock
151 Mountain at an elevation of 2042 m, coincident with Eunice Bluffs ~2100 m elevation, indicate
152 that wintertime (defined as November-May) temperatures fluctuate between -19.4 ⁰C and 24.4 ⁰C
153 (mean: 0.9 ⁰C) in high elevation regions of the Klamath Mountains while summertime (June-

154 October) temperatures remain relatively high (11.1 ºC to 31.6 ºC, mean: 12.7 ºC) (Garwood &
155 Welsh, 2007). The number of days with below freezing temperatures at the Eunice Bluff site in
156 the Klamath Mountains is therefore likely to be similar to or slightly greater than in the
157 Tablelands on account of the higher altitude and a high degree of diurnal temperature variation
158 (Arguez et al., 2010; Skinner et al., 2006); for example, precipitation in high elevation regions of
159 the Klamath Mountains such as the Trinity Alps occurs predominantly as snowfall between
160 November through May (Garwood & Welsh, 2007). The Klamath Mountains and Tablelands
161 sites therefore have similar mean annual precipitation but varying temperature regimes, and the
162 Tablelands sites and the higher elevation Klamath Mountain site experience substantially more
163 days below freezing than the lower elevation Klamath Mountains site.

164
165 **Figure 1.** Soil sampling locations marked by white stars. Exact latitude, longitude, and elevation
166 measurements are given in Table S1. Latitude and longitude (in decimal degrees), and elevation
167 (in meters) for each site are as follows— Devil's Punchbowl: 49.480056, -58.016667, 292, Trout
168 River Gulch: 49.479041, -57.980459, 155, Eunice Bluff: 41.339083, -133.587389, 2106, String
169 Bean Creek: 40.367500, -123.073033, 1174.

170   Time since deglaciation is commonly used as a proxy for soil age and by extension the
171 duration of soil weathering (Birkeland et al., 1991; Mahaney et al., 2009). The Klamath

172   Mountains Eunice Bluff soil was likely deglaciated ~12.1 ka based on paleolake records (Daniels
173   et al., 2005) and cosmogenic dating of glacial deposits (Dickey, 2016) in the nearby Trinity Alps.
174   The String Bean Creek soil in the Klamath Mountains is undated but developing in an area with
175   no record of glaciation and is therefore likely substantially older than the Eunice Bluff soil. In
176   the Tablelands, cosmogenic dating of boulders on a glacial moraine indicate that the Devil's
177   Punchbowl location was deglaciated at ~17.6 ka while cosmogenic dating of debris bench
178   material suggests the Trout River Gulch soil was deglaciated prior to ~20 ka (Osborn et al.,
179   2007).

180   Soil samples from both the Klamath Mountains and the Tablelands locations were
181   collected from soil pits excavated by hand using a pick and a shovel. Soil samples were selected
182   from the visually most weathered part of each soil profile, B soil horizons when present and C
183   soil horizons otherwise. Within the Klamath Mountains sites, samples were selected from a BC
184   horizon of the Eunice Bluff soil (23-33 cm depth interval) which was dug to point of refusal
185   (max depth: 53 cm), and from a Bt horizon of the String Bean Creek soil (40-50 cm depth
186   interval) which was dug into the C horizon (max depth: 130 cm). Soils from the Tablelands
187   (Devil's Punchbowl and Trout River Gulch) were not visually differentiated and were
188   determined to possess only C-horizons. Bulk soil samples were collected from the midpoint of
189   the Devil's Punchbowl soil (20-35 cm depth) that was dug to point of refusal (max depth: 50
190   cm), and from 35-50 cm depth in the Trout River Gulch soil pit which was dug until groundwater
191   started to fill the soil pit (max depth: 70cm). Soil material utilized for preparation of polished
192   thin section grain mounts for synchrotron analysis and for TEM analyses were prepared from the
193   same sample from each soil pit (Table S1).

194   *2.2 Synchrotron Analyses*

195   For synchrotron microprobe analyses, bulk soil samples were air-dried, sieved to <2 mm,
196   and prepared as grain mounts by Wagner Petrographics, Inc. To prepare the grain mounts, bulk
197   soil material was embedded in Buehler EpoThin 2 epoxy onto fused silica glass slides, cut to a
198   30-micron thickness, and polished to a 0.25-micron level using technical grade odorless mineral
199   spirits to limit potential chemical alteration during polishing.

200   X-ray microprobe analyses including µXRF, µXRD, and XANES were conducted on
201   beamline GSECARS 13-ID-E at the Advanced Photon Source at the Argonne National
202   Laboratory on the polished thin section grain mounts. Coupled µXRF/µXRD mapping was
203   conducted using a 10-millisecond dwell time with a 1.5 µm x 1.5 µm beam focused by a Rh-
204   coated Kirkpatrick-Baez focusing optics system with X-rays selected by a Si(111) cryo-cooled
205   double-crystal monochromator. µXRF data were collected using a Canberra SXD-7 7-element Si
206   drift detector (SDD) with Xspress3 electronics. µXRD patterns were collected in transmission
207   geometry using a Dectris Eiger 1M detector. For the coupled µXRF/µXRD analyses, the
208   wavelength of the incident X-ray microprobe beam was set to 0.6888 Å. Two coupled
209   µXRF/µXRD map sites were collected from each of the Eunice Bluff and Devil's Punchbowl
210   grain mounts and one from the String Bean Creek and Trout River Gulch grain mounts due to
211   time constraints at the beamline, resulting in a total of 3 at each of the Klamath and Tablelands
212   sites. µXRF/µXRD map locations were selected to encompass both potential secondary material
213   and primary mineral grains (Figure 2). The µXRF/µXRD maps were processed using the Larch
214   0.9.64 GSE MapViewer software (Newville, 2013).

215   Based on elemental distributions in the µXRF maps, points for additional µXRD and
216   XAFS analyses were selected to include both potential secondary material and primary minerals
217   (Figure 2; Table 1). Single point µXRD measurements were collected at these selected spots for
218   10 seconds. The 2D µXRD area detector patterns from selected points were processed using the
219   Dioptas 0.5.4 software (Prescher & Prakapenka, 2015) using CeO_2 as a calibration standard.
220   Prior to phase ID and quantification, the contribution to each µXRD pattern from the glass slide
221   and epoxy was removed by manually scaling the intensity of a 2D µXRD pattern collected from
222   a reference area on the glass slide that contained epoxy but no soil material to fit the background
223   of each µXRD measurement. Integration of the measured 2D µXRD patterns into 1D intensity vs
224   2θ patterns was done in Dioptas (Prescher & Prakapenka, 2015), allowing for confirmation that
225   the 1D conversion of the glass and epoxy contribution matches the background portion of the 1D
226   conversion of each 2D µXRD pattern. µXRD patterns that exhibited single-crystal like spots in
227   2D µXRD images, but did not possess powder-like rings, were excluded from analysis. When
228   single crystal-like diffraction spots were visible in 2D images of µXRD measurements that also
229   exhibited powder-like rings, the single crystal diffraction spots were masked prior to export of
230   1D XRD patterns for phase identification and Rietveld refinement. Phase identification was
231   initially performed within Dioptas software (Prescher & Prakapenka, 2015) using
232   Crystallography Open Database files (Graulis et al., 2009). Rietveld refinement following initial
233   phase identification was performed in Profex 5.1 (Doebelin & Kleeberg, 2015) using files from
234   the Crystallography Open Database (Graulis et al., 2009).

235   To examine Fe-oxidation states within primary minerals and secondary products, linear
236   combination fits (LCFs) were performed on XAFS spectra using the Larch XAS Viewer
237   software following energy calibration, background subtraction, and normalization (Newville,
238   2013). To determine the Fe-valence states of the analyzed phases from the measured XAFS
239   spectra, LCFs were performed from 7100 to 7160 eV using measurements from the single-
240   valence Fe^{2+} standards olivine (Fo_{80}), siderite, vivianite, and chromite, and goethite and
241   ferrihydrite as Fe^{3+} standards. The olivine and chromite standards were taken from the XANES
242   standards library included with the Hephaestus program in the Athena software suite; they were
243   collected at the ALS 10.3.2 beamline and are from (Marcus et al., 2008). The siderite, vivianite,
244   ferrihydrite, and goethite standards are from (Hansel et al., 2001) and were collected at the APS
245   13-ID-E beamline. All XAFS patterns used in fitting were adjusted for energy offsets prior to
246   fitting. E0 was set for zero valent Fe, measured using an Fe-foil reference standard, to a value of
247   7110.518 eV. LCFs do not demonstrate that a particular measured spot is composed of the
248   mineral standards utilized during fitting, but that the Fe valence state at the measured point is
249   best modelled by a combination of pre-selected standards representing potential ferric and
250   ferrous iron contributions. Linear combination fitting over the 7100 to 7160 eV range primarily
251   involves fitting the white line portion of the XAS spectra (Kelly et al., 2015).

252   *2.3 Transmission Electron Microscopy*

253   For TEM analyses, the clay-size (<2 µm diameter) fraction was extracted from bulk soil
254   material because incipient chemical alteration products including X-ray amorphous material
255   concentrate in this size fraction (Yesavage et al., 2015). To separate the <2 µm size fraction from
256   the bulk soil, 10 g of bulk soil were mixed with 25 mL of 18.2 MΩ DI water, sonicated for 30
257   minutes, vortexed, and allowed to settle for 1.5 hours after (Edwards & Bremner, 1967). The
258   supernatant was pipetted off, ACS reagent grade NaCl was added to the supernatant to a

259 concentration of 1 M to promote flocculation, and the samples were allowed to settle for 30
260 minutes. Samples were then centrifuged for 3 minutes at 8,000 rpm (8,228 x g) and the clear
261 supernatant was decanted from the clay-size fraction pellet. The clay-size fraction pellets were
262 then washed by adding 18.2 MΩ DI water, agitating the samples, and centrifuging at 8,000 rpm 3
263 more times to remove residual salt, frozen at -20°C for at least 12 hours, freeze-dried, then stored
264 at -20°C until analysis.

265   To prepare samples for TEM analysis, a small amount of the clay-size fraction was first
266 added to ~15 mL of a 70% ethanol and 30% water solution. The solution was sonicated for 5
267 minutes to disperse clay-size particle aggregates. A carbon-coated copper TEM grid (Ted Pella
268 Lacey Carbon Grids on 200 mesh Cu Grids, Part # 01894) was swirled in the ethanol and clay-
269 size material suspension and allowed to air dry. Prepared samples were analyzed using a Titan
270 300/80 (FEI) aberration corrected TEM at 300 kV accelerating voltage with a field emission
271 source and a Bruker XFlash 6T|30 electron dispersive spectroscopy (EDS) detector at the Eyring
272 Materials Center at Arizona State University. This instrument uses a CETCOR Cs corrector for
273 the objective lens to produce high resolution images with a spatial resolution of 0.7 Å. Imaging
274 and diffraction data were collected with Gatan One-View 4x4k digital camera. The selected area
275 aperture drive was not functioning properly during the available analysis time. While selected
276 area electron diffraction (SAED) patterns were collected to determine crystallinity, the presence
277 or absence of amorphous material was determined primarily from fast Fourier transform (FFT)
278 diffractograms of high-resolution TEM images. The 300 keV high beam energy utilized can
279 induce damage to sample material including causing sample materials to deform, shift, lose
280 crystallinity (amorphization), or crystallize. All images used for determining the presence and
281 characteristics of X-ray amorphous material (Figures 4-7, S59-S114), EDS measurements (Table
282 2, Appendix A), and d-spacing measurements (Table 3) are from TEM images and EDS
283 measurements in which no evidence of beam damage was observed; data acquisition from any
284 TEM imaging site was ended if beam damage was observed.

285   Due to the time-intensive nature of TEM work, 10 to 20 individual particles and particle
286 clumps (referred to as TEM sites, see Table S2, Figures S59 – S114) from the TEM sample from
287 each soil were examined to identify whether X-ray amorphous material was present and, if so,
288 the structural and chemical characteristics were studied. To examine the full range of X-ray
289 amorphous material, truly amorphous material and nanocrystallites were examined in a manner
290 like (Smith & Horgan, 2021). Truly amorphous refers to material without lattice fringes in high-
291 resolution TEM images and without discernable peaks or rings in SAED patterns or FFT
292 diffractograms. Nanocrystalline materials were defined as containing crystal or ordered domains
293 less than 100 nm in size that produce visible though typically diffuse peaks in SAED patterns or
294 FFT diffractograms (Smith & Horgan, 2021). Nanocrystallites can be present within the X-ray
295 amorphous component as XRD peaks become increasingly broad as crystallite size drops below
296 ~100 nm (Klug & Alexander, 1974) and become indistinguishable from amorphous background
297 scattering at crystallite sizes ≤10 nm (Holder & Schaak, 2019). TEM images, SAED patterns,
298 and FFT diffractograms were examined using Gatan Micrograph 3 software.

299   EDS chemical measurements of the examined X-ray amorphous material were
300 normalized to 100% without Cu or C due to potential contributions from the TEM grid material.
301 EDS quantification utilized a standardless Cliff-Lorimer technique with theoretical K-factors.
302 When possible, EDS measurements were acquired from areas that did not overlap with carbon

303   mesh material to limit the influence of carbon on chemical measurements. EDS measurement
304   spot size varied by site from as little as several nanometers in diameter to several tens of
305   nanometers across, and therefore the possibility exists that EDS measurements may have
306   captured multiple materials within each EDS measurement zone. Care was taken to examine
307   each TEM site during EDS acquisition for signs of beam damage induced changes; if beam
308   damage was observed during EDS acquisition the spectrum was discarded. EDS Measurements
309   were collected in TEM mode from materials determined to be amorphous and nanocrystalline
310   from TEM imaging. After identification of amorphous or nanocrystalline material, a beam stop
311   was put in place to limit sample electron exposure and potential beam damage from the 300 kV
312   beam to preserve sample material for subsequent EDS measurements. Initially, one EDS
313   measurement was typically collected from amorphous material or nanocrystallites at each TEM
314   site provided beam damage was not observed. After initial confirmation that globular amorphous
315   material was composed of amorphous silica (see results), EDS data were not collected from
316   additional globular material (Table S2). At one TEM site from the Devil's Punchbowl soil in the
317   Tablelands 3 EDS measurements were made on amorphous material from different points along
318   a rim surrounding a phyllosilicate aggregate (Figure S104). This was the only site where more
319   than one EDS measurement was acquired from amorphous material.

2.4 Statistical Analyses

321   A Shapiro-Wilk normality test was run on a) the oxidation state determined by LCF fits
322   of the synchrotron data for examined primary and secondary materials from the Klamath
323   Mountains and the Tablelands (i.e., all Klamath Mountain sites combined, all Tablelands sites
324   combined), b) Fe, Si, and Mg concentrations from EDS data of X-ray amorphous material from
325   the Klamath Mountains and the Tablelands (i.e., all Klamath Mountain sites combined, all
326   Tablelands sites combined) and the Gale crater X-ray amorphous material, and c) Fe, Si, and Mg
327   values for the individual amorphous and   nanocrystalline components of the terrestrial X-ray
328   amorphous material from the Klamath Mountains and the Tablelands (i.e., all Klamath Mountain
329   sites combined, all Tablelands sites combined). If normality was not rejected at a 95%
330   confidence level for all datasets being compared, then a two-sample t test was used when
331   comparing two sample groups and a Tukey-honest difference test if comparing three sample
332   groups. If normality was rejected at a 95% confidence level for at least one dataset being
333   compared, then the dataset distributions were compared using non-parametric tests, a Kruskal-
334   Wallis ANOVA test for comparing three sample groups or a Mann-Whitney test for comparing
335   two sample groups. See the supplementary online material for a schematic flow chart and
336   statistical analysis outputs (Figures S115-S140).

Figure 2. Synchtron microprobe results. A-F) µXRF heatmaps and XAFS/µXRD measurement spots from the Eunice Bluff soil (panels A and B) and String Bean Creek soil in the Klamath Mountains (panel C), and the Devil's Punchbowl soil (panels D and E) and the Trout River Gulch soil in the Tablelands (panel F). G) Rietveld fits of synchrotron µXRD patterns from weathering rinds from Eunice Bluff soil in the Klamath Mountains and the Trout River Gulch soil in the Tablelands. Phase abundances are given as wt.%, and the uncertainty is 2 standard deviations from the mean. Chi-squared values below 1 result from high degrees of noise in the fitted patterns due to the measurement times of 10 seconds.

346 **3 Results**

347   *3.1 Synchrotron Microprobe*

348   Synchrotron µXRF maps of thin sections of bulk soil material indicate that Fe is present
349 throughout the bulk soil in both primary and secondary material (Figure 2A-2F). Rietveld
350 refinements of µXRD patterns demonstrate the presence of lizardite and goethite in weathered
351 soil material in both Tablelands and Klamath Mountain soils (Figure 2G) with goethite present in
352 greater abundance in examined weathering rinds from the Klamath Mountains soils (59.0 ± 2.3 –
353 59.2 ± 2.5 wt.%) than the Tablelands soils (31.6 ± 2.1 – 33.2 ± 2.6 wt.%) (Figure 2G).
354 Refinements could not be performed on 2D µXRD patterns acquired from primary minerals due
355 to the lack of powder-like rings. Linear combination fits (LCF) of XAFS spectra (Appendix A;
356 Figures S1-S58) from points within the coupled µXRF and µXRD maps (Figure 2) yield Fe
357 oxidation states (Table 1) that contain statistically significantly higher Fe oxidation states than
358 primary material (Figures S116 – S119).

359 Table 1. Fe-oxidation states derived from linear combination fitting of Fe XAFS patterns.

361 Note: * Denotes weathering rind and/or potential secondary material, defined as diffuse Fe-
362 containing regions surrounding or between relatively euhedral grains.

363   *3.2 Transmission Electron Microscopy*

364 X-ray amorphous material was observed in all samples analyzed by TEM. The X-ray amorphous
365 component is composed of homogenous globular amorphous silica (Figure 3A) and a chemically
366 heterogenous assortment of nanospherical amorphous (Figure 3B) and nanocrystalline material
367 (Figure 3C). No examples of glassy textures were observed (i.e., angular X-ray amorphous
368 grains with a homogeneous tone) that would indicate the presence of primary amorphous
369 material.

370   The globular amorphous silica spherules are structurally and chemically homogenous,
371 lack distinct lattice fringes in HRTEM images (Figure 3A), and possess no indications for the
372 presence of crystallinity in the FFT and SAED diffractograms (Figure 3D). Some of the globular
373 amorphous silica spherules deviate from perfectly spherical but always have rounded and well-
374 defined edges (Figure 3A). EDS scans indicate that amorphous globulus are nearly pure SiO_2
375 with minor amounts (<3 atom %) of Mg, Fe, and Al (Table 2). Some amorphous silica globules

376 overlap crystalline material or other X-ray amorphous material, but amorphous silica globules
377 are not observed intermixed with or growing out of crystalline or other amorphous materials.
378 Globular material is present in 11 out of 27 examined sites from the two Tablelands soils in
379 aggregates up to ~2 µm across and present in 10 out of 19 examined sites from the Eunice Bluff
380 soil in the Klamath Mountains in aggregates up to ~400 nm across (e.g. Figure 4A - 4C).
381 Globular amorphous silica was not observed in any of the 11 examined TEM sites from the
382 String Bean Creek soil.

383
384 **Figure 3.** Examples of globular, clumpy nanospherical, and clumpy nanocrystalline X-ray
385 amorphous material. The labelled star denotes an energy dispersive spectroscopy measurement
386 point given in Table 3 and Figure 7. A) Globular amorphous material from the Devil's
387 Punchbowl soil (DvP TEM site 15, Table S2) in the Tablelands. B) Nanospherical clumpy
388 material from the Devil's Punchbowl site (DvP TEM Site 2: Table S2) in the Tablelands. C)
389 Nanocrystalline clumpy material from the String Bean Creek site (SBC TEM Site 11: Table S2)
390 in the Klamath Mountains, white arrows denote potential nanocrystalline phyllosilicates, labelled
391 start is the location of an EDS measurement spot in Table 2. D) SAED diffractogram from the
392 center of the mass of globules in Panel A. E) FFT diffractogram of panel B demonstrating
393 material is X-ray amorphous. F) FFT diffractogram of panel C.

402 [a] Spot # corresponds to labels in Figure 7.

403 [b] Spots 7, 13, and 22 are from Feldman et al. (Submitted)

404 Note: See Table S2 in the SOM for which TEM sites each EDS Spot # corresponds too.

405   A second X-ray amorphous component encompasses a heterogenous grouping of truly
406 amorphous, nanospherical material (Figure 3B) and nanocrystalline material (Figure 3C) that are
407 commonly but not universally found intermixed at the nanoscale (Figure 5), that lacks a regular
408 shape, possesses diffuse and rounded boundaries, and is chemically heterogenous.
409 Morphologically similar material lacking a well-defined euhedral shape and possessing diffuse
410 edges, sometimes with intermixed amorphous material and nanocrystallites, was termed "fluffy"
411 by Smith and Horgan (2021) and "clumpy" by Rampe et al. (2022), and we refer to this material
412 here as clumpy. Both nanospherical and nanocrystalline clumpy material is primarily observed
413 coating the edges of crystalline grains and crystalline aggregates (Figure 6A, 6B), although there
414 are two observed instances of isolated intermixed nanospherical and nanocrystalline aggregates
415 in the Eunice Bluff soil (e.g. Figure 6E-6H). In the Klamath Mountains, clumpy X-ray

416   amorphous material was observed in 10 out of 19 TEM sites from the Eunice Bluff soil and 1 out
417   of 11 TEM sites from the String Bean Creek soil. In the Tablelands, clumpy X-ray amorphous
418   material was observed in 4 out of 17 examined TEM sites from the Devil's Punchbowl soil and 4
419   out of 11 examined sites from the Trout River Gulch soil.

420
421   **Figure 5.** Intermixed nanospherical and nanocrystalline clumpy X-ray amorphous material.
422   Panels show HRTEM imagery and associated fast Fourier transform (FFT) diffractograms of
423   nanocrystalline domains within nanospherical material together comprising the clumpy
424   morphology material. White arrows denote nanocrystalline domains. Labelled stars denote
425   electron dispersive spectroscopy measurement spots given in Table 3, Figure 7, and Appendix A.
426   A) Intermixed nanocrystalline and nanospherical clumpy material from the Eunice Bluff soil (EB
427   Site 10: Table S2) in the Klamath Mountains B) FFT of panel A. C) Nanocrystalline packets
428   intermixed in nanospherical clumpy material from the Devil's Punchbowl soil (DvP Site 15:
429   Table S2) in the Tablelands. D) FFT of panel C.

430   The observed nanospherical material is composed of a mélange of tiny nodules (Figure
431 3B), morphologically like the "bubbly" texture of allophane (Iyoda et al., 2012; Ralston et al.,
432 2021), consistent with formation as an aqueous alteration product. Nanospherical material is
433 truly amorphous, lacking visible lattice fringes in HRTEM images (Figure 4B) or spots in FFT
434 diffractograms (Figure 4E). Nanospherical clumpy material exhibits a high degree of chemical
435 heterogeneity between aggregates, incorporating variable amounts of Si, Fe, Mg, and Al (Table
436 2), and minor amounts of other elements including Cr, Na, K, Ni, Ti, Mn, and Cl (Appendix B),
437 but is on average more Si-rich than Fe-rich (Table 2).

438   Nanocrystalline clumpy material is primarily composed of packets of tiny, equant
439 crystallites typically <20 nm across (Figure 3C, 4A, 4C). Although Si, Mg, and Al are present in
440 variable amounts, nanocrystalline clumpy material in both the Klamath Mountains and
441 Tablelands are uniformly Fe-rich (≥16.50 atom %) and, with one exception in the Tablelands, is
442 more Fe-rich than Si-rich (Table 2).

Figure 6. Examples of clumpy X-ray amorphous material on crystalline grain edges and as an
independent particle. Clumpy nanospherical material forming at the edges of an aggregate of
primary crystalline grains that includes phyllosilicate flakes and tubular serpentine, likely
chrysotile, laths (A-D) and intermixed clumpy nanospherical and nanocrystalline material
occurring as an isolated precipitate (E-H). Numbered white stars denote EDS measurement spots
given in Table 3 and Figure 7. A) Aggregate mass of clay particles and amorphous material from
the Devil's Punchbowl soil in the Tablelands (DvP TEM Site 17, Table S2). B) Higher
magnification image of nanospherical amorphous material on the edge of the crystalline
aggregate in panel A. C) Selected area electron diffractogram from the center of the crystalline
mass in panel A. D) fast Fourier transform (FFT) diffractogram of nanospherical material shown
in panel B. E) Isolated aggregate of intermixed nanospherical and nanocrystalline material from
the Eunice Bluff soil in the Klamath Mountains (EB TEM Site 10, Table S2). F) Higher
magnification image of intermixed nanospherical and nanocrystalline material from panel E. G)
FFT diffractogram of nanocrystalline material from panel F. H) FFT diffractogram of
nanocrystalline material from panel F.

459   Gale crater amorphous material is overall chemically similar to the X-ray amorphous
460   material from the Tablelands and relatively dissimilar to Klamath Mountains X-ray amorphous
461   material (Figure 7). At a 95% confidence interval, Fe, Si, and Mg concentrations from the
462   Tablelands and Klamath Mountains clumpy X-ray amorphous material exhibit normal
463   distributions for Fe content but not for Si and Mg content, and Gale crater X-ray amorphous
464   material exhibits normality for Si and Mg but not for Fe (Figures S123 – S125). Therefore, a
465   non-parametric Kruskal-Wallis ANOVA test was employed to examine differences in Fe, Si, and
466   Mg content between the Tablelands, Klamath Mountains, and martian X-ray amorphous
467   material. These tests indicate that Fe, Si, and Mg concentrations in the clumpy material from the
468   Tablelands and Gale crater are statistically indistinguishable, that Si and Mg content is
469   significantly elevated in X-ray amorphous material from the Tablelands compared to the
470   Klamath Mountains while Fe content does not exhibit significant differences, and that Gale
471   crater X-ray amorphous material exhibits significantly lower Fe and higher Si and Mg values
472   than Klamath Mountain X-ray amorphous material (Figures S126 – S128).

473
474   **Figure 7.** Plots of Si versus Fe (a) and Mg versus Fe (b) allow a comparison of the Si, Mg, and
475   Fe concentrations of X-ray amorphous material from Gale crater (Rampe et al., 2020 and Thorpe
476   et al., 2020), the Tablelands, and the Klamath Mountains. Gale crater and Tablelands amorphous
477   material are not statistically differentiable, i.e. no statistically significant difference in Fe (Figure
478   S126), Si (Figure S127), or Mg (Figure S128) content whereas the Gale crater and Klamath
479   Mountains materials show a larger difference, i.e. statistically significant differences in Fe

480 (Figure S126), Si (Figure S127), and Mg (Figure S128). This result supports the inference that
481 X-ray amorphous material in Gale crater is more likely to have formed in a colder environment.
482 Gale crater X-ray amorphous material oxide wt.% chemistry and associated abbreviations can be
483 found in (Rampe et al., 2020; Thorpe et al., 2022). EDS chemical data for terrestrial samples is
484 given in Table 3.

485 Within the nanocrystallite component, while no nanocrystallites exhibit d-spacings
486 representative of ideal ferric oxides and oxyhydroxides (Table 3), all nanocrystallites exhibit at
487 least two lattice planes within 0.1 Å of d-spacings for the Fe^{3+}-oxyhydroxide goethite (Table 3);
488 overlap between goethite and ferrihydrite peaks and potential growth of goethite from
489 ferrihydrite precursors (Cudennec & Lecerf, 2006) suggest that ferrihydrite presence may also be
490 present. Elongate curvilinear nanocrystallites with morphologies like the elongate curvilinear
491 phyllosilicates observed by (Smith & Horgan, 2021) and (Rampe et al., 2022) in natural
492 sediments and by (Ralston et al., 2021) forming within synthetic Fe-rich allophane were
493 observed in clay-size fraction material from the String Bean Creek soil (Figure 3C). D-spacings
494 from the associated FFT diffractogram (Figure 3F) were consistent with nontronite XRD peaks
495 ~3.8 Å, 2.7 Å, and 2.2 Å (Baker & Strawn, 2014) and a ~1.5 Å peak consistent with the presence
496 of a dioctahedral smectite (060) plane (Moore & Reynolds, 1997). These results suggest the
497 presence of nanocrystalline smectites in the String Bean Creek soil clay-size fraction (Table 3).
498 The presence of nanocrystalline smectites in the String Bean Creek soil is also consistent with
499 the presence of smectites in the String Bean Creek soil clay-size fraction and bulk soil as
500 determined by powder XRD (Feldman et al., Submitted for Review). Similar evidence for the
501 presence of potential secondary nanocrystalline phyllosilicates within X-ray amorphous material
502 was not observed in the Eunice Bluff soil or Tablelands soils.

503 **Table 3.** A summary of peak positions from the literature for ferrihydrite (F), goethite (G), and
504 nontronite (N) compared to lattice fringe d-spacings for nanocrystalline domains where EDS
505 measurements were taken (see Table 1 for EDS measurements)

506 [1]D-spacings for Ferrihydrite (6 line) and Ferrihydrite (2 line) are from Drits et al. (1993).

507 [2]D-spacings for Ferrihydrite (Michel) were extracted from published .cif files from recent work
508 (Michel et al., 2007) suggesting the ferrihydrite structural model is like an Fe-substituted
509 akdalaite structure.
510 [3]D-spacings for goethite are from the handbook for mineralogy (Anthony et al., 2001) and from
511 Nagai et al. (2003)
512 [4]D-spacings for Nontronite (BS) are from Baker and Strawn (2014).
513 Note: TEM site #s correspond to site numbers given in Table S2 in the SOM. An EDS spot # of
514 NA indicates that no EDS measurements were made.

4 Discussion

516   X-ray amorphous material represents a poorly understood aspect of martian mineral
517 assemblages potentially useful as an indicator for past environmental conditions on Mars. The
518 comparison of X-ray amorphous material from the subarctic climate Tablelands and the
519 Mediterranean climate Klamath Mountain soils here indicates differences that provide important
520 indicators for formation conditions for both returned samples and *in situ* analyses from Mars.

521   Globular amorphous silica is present in the high elevation (~2100 m) Eunice Bluff soil
522 (Figure 4A) and the Tablelands soils (Figure 4B, 4C) that experience extended periods of
523 freezing conditions (Garwood & Welsh, 2007) but not within the lower elevation String Bean
524 Creek soil (~1120 m) that does not experience similar extended periods of sub-freezing
525 conditions (Arguez et al., 2010; Skinner et al., 2006). Globular amorphous silica does not appear
526 intermixed with or growing out of crystalline material, consistent with precipitation out of
527 solution. The presence of amorphous silica only in soils where wintertime temperatures are
528 consistently below freezing is consistent with lower temperatures decreasing amorphous SiO_2
529 solubility (e.g., Gunnarson and Arnórsson, 2000) coupled with freezing of soil-pore water
530 increasing SiO_2 concentration in solution above amorphous SiO_2 saturation. Similar freeze thaw
531 cycling has been demonstrated to promote amorphous silica precipitation in laboratory settings
532 (Dietzel, 2005). Consistent with the proposed importance of freezing temperatures on globular
533 amorphous silica formation, hydrated opaline silica coatings have been shown to be prevalent in
534 glacially derived volcanic sediments forming under high-elevation cold climates in Cascadia
535 from silica precipitating out of solution (Rutledge et al., 2018). Amorphous silica has also been
536 documented within high-elevation cold climate pro-glacial soils and lake sediments from sites
537 deglaciated after the Little Ice Age in the Three Sisters Volcanic complex in Oregon (Smith &
538 Horgan, 2021) in cryogenic Antarctic soils (Simas et al., 2006), and in soils on the Arctic
539 Archipelago of Svalbard (Hausrath et al., 2008). Amorphous silica therefore appears to be a
540 robust indicator for the presence of extended periods of freeze-thaw conditions that could be
541 useful in identifying the past presence of such conditions in samples returned from Mars.

542   The chemical composition of clumpy X-ray amorphous material likewise exhibits a
543 robust relationship with temperature. Clumpy X-ray amorphous material in the subarctic
544 Tablelands soils incorporates significantly greater amounts of Si and Mg than in the warmer
545 Klamath Mountains soils (Figure 7, S127, S128) and is statistically undistinguishable from Gale
546 crater X-ray amorphous material (Figures S126 – 128). Similar chemical trends are also apparent
547 in the individual nanocrystalline and nanospherical components of the terrestrial soils, with
548 nanocrystallite material in the subarctic Tablelands soils exhibiting significantly elevated Si and
549 Mg and nanospherical material exhibiting significantly higher Mg-content than is found in

550   clumpy X-ray amorphous material in the warmer Klamath Mountains (Figures 7, S135 – S140).
551   Greater incorporation of relatively immobile elements such as Fe into X-ray amorphous material
552   and particularly into nanocrystallites in the warmer Klamath Mountain soils (e.g. Figure S138)
553   while more mobile elements (Mg, Si) exhibit greater incorporation into X-ray amorphous
554   material in the colder Tablelands soils is consistent with similarly Fe-containing, Mg-containing,
555   but generally more Si-rich X-ray amorphous material in Gale crater (Rampe et al., 2020; Thorpe
556   et al., 2022) forming under cold and wet conditions.

557   Fast Fourier transforms from all examined nanocrystallite-containing X-ray amorphous
558   material exhibit at least two d-spacings within 0.1 Å of ideal d-spacings for the Fe^{3+}-
559   oxyhydroxide goethite (Table 3); overlap between goethite and ferrihydrite peaks and potential
560   growth of goethite from ferrihydrite precursors (Cudennec & Lecerf, 2006) suggest that
561   ferrihydrite presence may also be present. The presence of goethite nanocrystallites indicated by
562   d-spacings in TEM analyses is consistent with the presence of goethite in µXRD of Klamath
563   Mountain soil weathering rinds (59.0 ± 2.3 – 59.2 ± 2.5 wt.%) and in the Tablelands soils (31.6 –
564   33.2 ± 2.6 wt.%) (Figure 2F). The more Fe-rich nature of the nanocrystallites in the Klamath
565   mountains (Figures 7A, S135) than the Tablelands (Figures 7A, S136) could therefore be due to
566   the greater presence of goethite observed in the synchrotron analyses.

567   Elongate curvilinear nanocrystallites, morphologically consistent with nanocrystalline
568   phyllosilicates (Rampe et al., 2022; Smith & Horgan, 2021), with lattice fringe d-spacings
569   consistent with observed XRD peaks for the Fe-rich dioctahedral smectite nontronite at ~3.8 Å,
570   ~2.7 Å, and ~2.2 Å (Baker & Strawn, 2014), and ~1.5 Å (Moore & Reynolds, 1997) are only
571   observed in the String Bean Creek soil (Figure 3C, Table 3). The String Bean Creek soil has
572   been developing under a warmer climate (mean annual temperature: ~12.8 ºC) than all other soils
573   examined in this study (Eunice Bluff: mean annual temperature <12.8 ºC, Tablelands soils: mean
574   annual temperature <3.9 ºC) that likely lacks substantial periods of below freezing conditions
575   (Skinner et al., 2006), and due to a lack of documented glaciation in the southern Klamath
576   Mountains has likely been undergoing pedogenesis for a longer time period than the other
577   examined soils. The presence of nanocrystalline smectites only within the oldest and warmest
578   soil is consistent with previous work demonstrating that longer durations of aqueous alteration
579   under warmer temperatures promote smectite formation (e.g., Bishop et al. 2018). The presence
580   of secondary nanocrystalline phyllosilicates within the X-ray amorphous component is
581   potentially consistent with incipient smectite development from amorphous precursors, like
582   previous work in Klamath Mountain serpentine soils that proposed formation of smectites from
583   amorphous gel precursors (Istok & Harward, 1982).

584   Secondary X-ray amorphous material in Fe-rich and Al-poor environments chemically
585   relevant to past martian aqueous alteration suggest temperature indicators that will be valuable
586   for analyzing samples returned from Mars. Detection of globular amorphous silica and mixed
587   composition nanospherical and nanocrystalline material with high concentrations of mobile
588   elements (e.g., Mg, Si) would be consistent with colder alteration conditions where freezing may
589   occur seasonally, whereas an absence of amorphous silica, more purely Fe-rich nanocrystallites
590   with lower incorporation of more mobile (Mg, Si) elements, and the presence of secondary
591   phyllosilicates would be indicators of warmer conditions where freezing temperatures are
592   uncommon.

593   Although the scales of observation are different, the chemical trends observed here can
594   also assist in interpreting remote and *in-situ* observations of X-ray amorphous material on Mars
595   for clues to temperature conditions during formation. In these examined terrestrial soils, the
596   presence of amorphous silica correlates with seasonal sub-freezing conditions. That result is
597   consistent with amorphous silica in Gale crater sediments (Rampe et al., 2020), at Gusev crater
598   (Ruff & Hamilton, 2017), Jezero crater (Tarnas et al., 2019), and elsewhere across the martian
599   surface (Milliken et al., 2008) resulting from precipitation from silica-rich fluids under
600   predominantly cold and icy conditions, as has been proposed for hydrated amorphous silica
601   fracture halos within Gale crater (Gabriel et al., 2023). Greater Si abundance within Fe-
602   containing X-ray amorphous material from colder regions is consistent with the typically greater
603   concentrations of Si than Fe within Gale crater X-ray amorphous material (Rampe et al., 2020;
604   Smith et al., 2021; Thorpe et al., 2022) resulting from formation under cold and alternately wet
605   and icy conditions. The coupled presence of Fe-rich nanocrystallites within a more Si-rich
606   nanospherical amorphous matrix and pure amorphous silica in the subarctic Tablelands soils is
607   compositionally and chemically like the mixed nanophase Fe-oxide and amorphous silica
608   assemblage present in Gusev crater previously suggested to result from aqueous alteration under
609   a relatively cold climate (Ruff & Hamilton, 2017). Nanocrystalline smectites in these Al-poor
610   soils are only found in the warmest and oldest soil environment that lacks extended periods of
611   sub-freezing conditions, consistent with the abundant smectites in Gale crater (T F Bristow et al.,
612   2021; Thomas F. Bristow et al., 2018; Rampe et al., 2020; Thorpe et al., 2022) and elsewhere on
613   the martian surface (Ehlmann & Edwards, 2014) indicating at least intermittent warm periods
614   (Bishop et al., 2018).

5 Conclusions

616   The nature of Mars' early climate and aqueous conditions are imprinted in the secondary
617   mineral assemblage, including in X-ray amorphous material, present in abundances up to 73
618   wt.% in Gale crater ancient fluviolacustrine and aeolian sedimentary rocks (Rampe et al., 2020;
619   Thorpe et al., 2022). Transmission electron microscopy and synchrotron microprobe techniques
620   results from the X-ray amorphous material from the cold subarctic climate of the Tablelands of
621   Newfoundland Canada and the warmer Mediterranean climate of the Klamath Mountains of
622   California demonstrate clear temperature-related trends in the composition of these materials.
623   The formation of amorphous silica and greater retention of the more mobile Si and Mg cations
624   (Gaudin et al., 2011) within Fe-containing X-ray amorphous material, particularly in the
625   formation of mixed-composition nanocrystallites, is observed under colder conditions. Warmer
626   conditions correlate with the formation of Fe-rich but relatively Mg- and Si-poor X-ray
627   amorphous material and greater formation of more Fe-rich Fe^{3+}-oxyhydroxide nanocrystallites
628   and promote the formation of nanocrystalline phyllosilicates.

629   These results are consistent with formation of the abundant Fe- and Si-rich but generally
630   more Si- than Fe-rich, sometimes Mg-rich, and Al-poor X-ray amorphous material in Gale crater
631   (Rampe et al., 2020; Thorpe et al., 2022) and X-ray amorphous material elsewhere on Mars
632   (Ruff & Hamilton, 2017; Weitz et al., 2014) forming through aqueous alteration under generally
633   cold and alternately icy and wet conditions. Abundant amorphous silica formation and
634   incorporation of SiO_2 into X-ray amorphous material in returned martian samples, especially into
635   nanocrystallite containing material, would further support formation under cold aqueous
636   alteration conditions. This work demonstrates the influence of temperature conditions on the

637 structure and chemistry of X-ray amorphous material and that the chemical composition of such
638 material could provide a useful proxy for estimating environmental conditions during formation
639 in terrestrial and martian settings. Microscale analyses such as those presented here will be
640 essential for evaluating returned martian samples and interpreting the implications of
641 mineralogical and chemical heterogeneity in terms of past martian environmental conditions.
