## Abstract

Climate change threatens the resource adequacy of future power systems. Existing research and practice lack frameworks for identifying decarbonization pathways that are robust to climate-related uncertainty. We create such an analytical framework, then use it to assess the robustness of alternative pathways to achieving 60% emissions reductions from 2022 levels by 2040 for the Western U.S. power system. Our framework integrates power system planning and resource adequacy models with 100 climate realizations from a large climate ensemble. Climate realizations drive electricity demand; thermal plant availability; and wind, solar, and hydropower generation. Among five initial

047 decarbonization pathways, all exhibit modest to significant resource ade-  
048 quacy failures under climate realizations in 2040, but certain pathways  
049 experience significantly less resource adequacy failures at little addi-  
050 tional cost relative to other pathways. By identifying and planning for  
051 an extreme climate realization that drives the largest resource ade-  
052 quacy failures across our pathways, we produce a new decarbonization  
053 pathway that has no resource adequacy failures under any climate real-  
054 izations. Our framework can help planners adapt to climate change, and  
055 offers a unique bridge between energy system and climate modelling.

## 061 1 Introduction

062 Rapidly transitioning to a decarbonized electric power sector is crucial to  
063 aggressively mitigate climate change and meet emissions reductions targets  
064 [1, 2]. In the United States, the Inflation Reduction Act (IRA) is poised to  
065 accelerate low-carbon investments in the power sector, which could approach  
066 370 billion USD by 2033 [3, 4]. Which power sector decarbonization pathway  
067 will be taken remains uncertain, where a pathway is defined by where, when,  
068 and what decarbonization investments occur [5–11]. As they decarbonize, bulk  
069 (or transmission-scale) power systems will be increasingly affected by climate  
070 change [12]. Increasing ambient air temperatures will increase peak and total  
071 electricity demand [13–15] and reduce available capacity from thermal and  
072 solar generators [13, 16–18]. Wind, solar, and precipitation changes will also  
073 affect wind, solar, and hydropower generation potential [13, 19–21]. These  
074 effects could compound to undermine resource adequacy (RA), or a system’s  
075 ability to continually balance electricity supply and demand [22–24]. Under-  
076 standing the vulnerability of decarbonizing power systems to potential future  
077 climate realizations is critical for achieving reliable, affordable, and clean power  
078 systems - the focus of our study [9, 25].

080 To account for decarbonization- and climate-related uncertainty in invest-  
081 ment decisions, prior literature optimizes capacity investment decisions given  
082 different decarbonization pathways and future climate scenarios [5, 9, 26–32].  
083 This literature uses sensitivity or scenario analysis to incorporate climate-  
084 related uncertainty within deterministic modeling frameworks. For instance,  
085 Fonseca et al. [5] sample 3 of 20 global climate models (GCMs) to include as  
086 scenarios in a deterministic long-term power system planning model. In other  
087 words, this literature aims to improve investment decisions by improving pre-  
088 dictions of future weather within standard modeling frameworks. But climate  
089 change poses deep uncertainty [33], which undermines the value of methods  
090 focused on better predictions [34], particularly for power system planning  
091 models that must significantly simplify uncertainty to remain computationally  
092 tractable. In the near-term (prior to 2050), inter-annual (or internal) climate

variability, which is driven by the dynamics of the climate system and sensitive to initial conditions [35–38], is the primary source of climate-related uncertainty [37, 39] (as opposed to model or emissions scenario uncertainty [40]). Inter-annual variability superimposed on a non-stationary background climate and emission trajectory leads to deep uncertainty on climate impacts [41]. Under deep uncertainty, methods instead focused on identifying robust strategies or alternatives are better suited to informing decisions [34]. Such decision support is urgently needed by power system planners and regulators, who are tasked with ensuring resource adequacy across the full range of potential future climate realizations, which combine secular trends and inter-annual climate variability [38]. Recent rolling outages in California and Texas [42, 43] and resource adequacy warnings elsewhere in the United States [44] underscore this urgency.

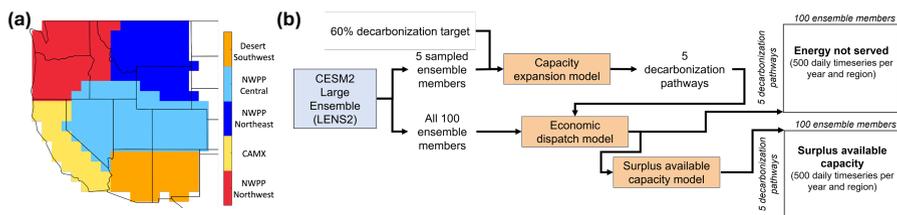

In response to these needs, we construct a new analytical framework for planning decarbonizing power systems under deep climate uncertainty by drawing on a concept from the decision science literature: robust decision making (RDM) [34]. RDM has been used to inform climate adaptation strategies, e.g. in water resources management [45–51]. It has also been used in the power sector, e.g. to evaluate policy strategies for European power systems against shocks [52]. But our framework is the first to apply RDM to planning decarbonizing power systems under deep climate uncertainty. By integrating power system planning and operational models with potential climate realizations from a single model initial-condition large ensemble (SMILE) [53, 54], our framework generates alternative decarbonization pathways; characterizes the vulnerability of and trade-offs between those pathways under potential climate realizations; and uses generated insights to identify new alternative decarbonization pathways that are robust to climate-related uncertainty (Figure 1). SMILEs have limited prior use in power systems research [55, 56] even though they are designed to sample inter-annual variability and provide many realizations of future climate, encoding multiple extreme events and a range of possible meteorological projections [57, 58].

We use our framework to answer: how can we design decarbonizing power systems to be robust against deep climate uncertainty? We conduct our study for the U.S. Western Interconnect, which we divide into five subregions per Western Electricity Coordinating Council’s resource adequacy assessments (Figure E.1, [59]). We use 100 members from the Community Earth System Model 2 (CESM2) Large Ensemble (LENS2) through 2040, which was driven by the SSP3-7.0 emissions scenario and reaches 1.65°C of global warming by 2040 relative to pre-industrial [60]. For each ensemble member, we obtain surface air temperatures, relative humidity, surface solar radiation, 10m wind speeds, and surface runoff at daily and 1° spatial resolution (approx. 100 km by 100 km) through 2040 across our study region. While this resolution is lower than what is preferred for power system modeling, higher resolution climate datasets often do not sample as large of a range of internal climate variability as LENS2, particularly in the time-span of interest to us (through 2040) and

4 *RDM decarbonization*

139 when focused on extreme events. In selecting LENS2, we also emphasize inter-  
 140 nal variability over climate response uncertainty. For each ensemble member,  
 141 we translate meteorological variables to spatially-explicit timeseries of elec-  
 142 tricity demand; maximum potential wind, solar, and hydropower generation;  
 143 and thermal generator deratings and forced outage rates. To analyze the vul-  
 144 nerability and trade-offs of alternative decarbonization pathways, we generate  
 145 five decarbonization pathways by running a capacity expansion (or long-term  
 146 planning) model of the Western Interconnect using power system variables  
 147 from five sampled ensemble members. Our decarbonization pathways reduce  
 148 interconnect-wide power system CO<sub>2</sub> emissions by 60% from 2022 levels by  
 149 2040. For each decarbonization pathway, we approximate its regional resource  
 150 adequacy in 2040 under each of the 100 ensemble members using economic  
 151 dispatch and surplus available capacity models. From this large set of alter-  
 152 native future systems and climate realizations, we examine vulnerabilities and  
 153 trade-offs of these decarbonization pathways across potential climate realiza-  
 154 tions. Finally, we identify a future climate realization that generates the largest  
 155 resource adequacy failures across decarbonization pathways in 2040, then use  
 156 that climate realization to generate a new decarbonization pathway robust to  
 157 all 100 ensemble members.

 174 into 5 sub-regions (differentiated by color). Blocks at edges of interconnect  
 175 correspond to LENS2 grid cells. (b) Our analytical framework integrates 100  
 176 ensemble members (or climate realizations) from the LENS2 dataset with  
 177 power system capacity expansion, economic dispatch, and surplus available  
 178 capacity (SAC) models. For each region, this framework yields 500 daily time-  
 179 series of energy not served and surplus available capacity in 2040, or 1 daily  
 180 timeseries for each climate realization, decarbonization pathway, and metric.  
 181 Not shown is identification of an extreme 2040 climate realization, which is  
 182 then fed back into the capacity expansion model to generate a new decarbo-  
 183 nization pathway.

184

## 2 Methods 185

### 2.1 Robust Decision-making Framework 186

We use robust decision-making (RDM) to quantify the robustness of alternative decarbonization pathways in the Western Interconnect power system to potential future climate realizations. We first conduct exploratory modeling to generate five decarbonization pathways for the Western Interconnect using a capacity expansion (or long-term planning) model (Section 2.2). We then stress test each decarbonization pathway to all 100 LENS2 ensemble members (Section 2.4). For each pathway and ensemble member, we approximate resource adequacy by quantifying daily Surplus Available Capacity (SAC) and Energy Not Served (ENS) in 2040 (Section 2.3). Finally, we identify the climate ensemble member that drives the largest combined energy not served (ENS) across decarbonization pathways in California (our largest load region) in 2040; rerun our planning model using that ensemble member; and quantify our resource adequacy metrics for that pathway against all 100 climate ensemble members. 187

### 2.2 Capacity Expansion Model and Decarbonization Pathways 204

To generate alternative decarbonization pathways, we use a capacity expansion (or long-term planning) model. We run the capacity expansion model (CEM) in two year increments from 2023 to 2040, capturing coincident, spatially-resolved meteorology and hydrology for each year (Section 2.4). The CEM is a deterministic linear program that minimizes fixed plus variable costs by deciding investment in wind plants, solar plants, and natural gas combined cycle (NGCC) plants with or without carbon capture and sequestration (CCS), and inter-regional transmission. These investment decisions differentiate our "decarbonization pathways". The CEM also optimizes operation of existing and new generators, and optimizes inter-regional transmission flows using the simplified transport method. All generator capacity investment decisions occur at the LENS2 grid cell level, i.e. on a 100 by 100 km grid across our study region, while transmission investments occur at inter-regional levels. We constrain thermal plant investments to grid cells that already contain large thermal units. Given the immature state of CCS technology, we allow the CEM to invest in NGCC or coal with CCS beginning in 2031. While we recognize the important role of grid-scale storage in decarbonizing power systems, our climate data is only available at daily resolution (Section 2.4). As such, we cannot model intra-day storage. 205

218  
219  
220  
221  
222  
223  
224  
225

The CEM includes numerous system- and generator-level constraints. At the system level, the CEM balances regional supply (generation plus imports minus exports) and demand each day. To approximate system reliability standards, the CEM includes a 13% planning reserve margin, which requires derated capacity to exceed peak demand by at least 13%. Derated capacity 226  
227  
228  
229  
230

231 accounts for wind and solar generation potential; a fixed 5% forced outage  
232 rate for wind and solar generators; temperature-dependent FORs for thermal  
233 and hydropower plants; and weather-driven deratings of combustion turbine,  
234 combined cycle, and coal-fired plants. At the generator level, wind and solar  
235 generation is limited by daily, spatially-specific wind and solar capacity factors  
236 (Section 2.4); hydropower generation is constrained by subregional monthly  
237 total generation; and generation from combustion turbine, combined cycle, and  
238 coal-fired plants is limited by daily, spatially-specific meteorology.

239 With the CEM, we generate five decarbonization pathways that each reduce  
240 interconnect-wide CO<sub>2</sub> emissions by 60% from 2022 levels by 2040. To create  
241 these five pathways, we use meteorological timeseries from five sampled LENS2  
242 members. These ensemble members are sampled to capture a range of warming  
243 within the LENS2 ensemble. Specifically, we quantify warming level based on  
244 the difference between historic (1985-2015) and mid-century (2035-2065) mean  
245 surface temperature and relative humidity [61]. Warming and relative humidity  
246 levels vary from 1.5 °C to 2.75 °C and 0.1 to -1.79, respectively, across sampled  
247 ensemble members (Figure B.10). In using five sampled ensemble members,  
248 our purpose is to create heterogeneous decarbonization pathways that could all  
249 reach a given decarbonization target, then assess the pathways' vulnerabilities,  
250 trade-offs, and robustness. We do not create a pathway for each ensemble  
251 member because creating pathways that span all climate- and decarbonization-  
252 related uncertainty is not computationally tractable. Rather, researchers and  
253 practitioners explore a subset of this uncertainty in analyses and long-term  
254 plans. We therefore demonstrate our framework in a similar context, i.e. on  
255 pathways that consider a subset of relevant uncertainty.

256

### 257 **2.3 Decarbonization Pathways and Resource Adequacy** 258 **under Potential Climate Realizations** 259

260 From our CEM, we obtain five decarbonization pathways, each planned for one  
261 of five sampled ensemble members. To understand the vulnerability of each  
262 decarbonization pathway to other potential ensemble members, we approxi-  
263 mate the resource adequacy of each decarbonization pathway against all 100  
264 ensemble members (or climate realizations) from LENS2. Because LENS2  
265 provides daily values, we are unable to quantify resource adequacy (RA) of  
266 the Western Interconnect at an hourly basis using a standard probabilistic  
267 RA model. Instead, we approximate resource adequacy by quantifying daily  
268 Surplus Available Capacity (SAC) and Energy Not Served (ENS).

269 To calculate daily ENS, we run an economic dispatch model (EDM) for  
270 each decarbonization pathway output by our capacity expansion model in 2040.  
271 The EDM minimizes the sum of operating, CO<sub>2</sub> emission, inter-regional trans-  
272 mission, and ENS costs by optimizing generation, inter-regional transmission,  
273 and ENS decision variables. CO<sub>2</sub> emission costs include a decarbonization-  
274 pathway-specific CO<sub>2</sub> price necessary to achieve the relevant CO<sub>2</sub> emissions  
275 cap in that year; we include this price instead of a cap to avoid infeasibility in  
276 the EDM in climate realizations that preclude meeting the CO<sub>2</sub> cap. The EDM

includes several constraints from the CEM, including balancing supply and demand within each of our five subregions while accounting for transmission inflows and outflows; constraining regional monthly hydropower generation to an energy budget; constraining wind and solar generation to spatially- and temporally-differentiated capacity factors; and constraining fossil-based thermal plant generation based on capacity deratings. Since we cannot probabilistically sample generator outages like hourly resource adequacy models, the EDM instead derates generators' capacities based on temperature-dependent or fixed forced outage rates (FORs). We run the EDM for a 1-year optimization horizon. Inputs to the EDM include a decarbonization pathway and variables driven by the given climate ensemble member (i.e., daily electricity demand, monthly hydroelectric generation, daily solar and wind capacity factors, and daily thermal plant forced outage rates and derates). See SI.F for the full EDM formulation and key parameters.

From the EDM output, we directly obtain daily ENS and calculate SAC for each region. SAC equals daily available non-hydropower capacity, hydropower generation, and transmission imports minus demand and transmission exports for each region. In this way, SAC indicates excess supply available in a region to satisfy unexpected increases in demand. The lower the SAC, the greater the risk of a supply shortfall, suggesting lower resource adequacy. Prior research has used a net load metric as a proxy for resource adequacy [55, 62]. Our SAC extends the net load metric by capturing not just daily wind and solar generation potential, but also accounts for optimized hydroelectric dispatch; temperature dependent outages in thermal and hydroelectric power plants; capacity deratings in fossil-based thermal power plants; and electricity flows between regions. See SI.G for more details on SAC calculation.

## 2.4 LENS2 Climate Data and Conversion to Power System Variables

In the near-term (prior to 2050), internal variability (versus model or emissions scenario uncertainty) is the primary source of climate-related uncertainty [37, 39]. To capture the role of internal variability in driving potential climates through 2040, we use the CESM2 Large Ensemble (LENS2) [60]. This dataset is a single model initial-condition large ensemble (SMILE) following the SSP3-7.0 emissions trajectory. We treat this global emissions trajectory as independent of our system's emissions trajectory, as internal variability - not emissions uncertainty - is the primary source of uncertainty over our study period.

The LENS2 dataset consists of 100 ensemble members which are split into 2 groups each consisting of 50 realizations, where each group is driven by one forcing condition. Each of the 50 realizations in the two groups are initiated from different initial conditions sampled to reflect micro and macro perturbations in the pre-industrial control simulation. Unless noted otherwise, all the variables with a specified frequency represent an average over the inherent time periods, e.g. daily temperature is daily averaged temperatures and monthly runoffs are monthly averaged runoffs. We obtain daily surface temperature,

323 10m wind speed, surface downwelling solar flux, surface atmospheric pressure,  
324 surface relative humidity, and monthly surface liquid runoff from 1980-2050  
325 for each ensemble member. We obtain these variables at the highest spatial  
326 resolution possible, at a 100 km by 100 km grid. While this spatial and tem-  
327 poral resolution is lower than what is preferred for power system modeling,  
328 higher resolution climate datasets (e.g., from statistical or dynamical down-  
329 scaling) often do not sample as large of a range of internal climate variability  
330 as LENS2, particularly in the time-span of interest to us (through 2040) and  
331 when focusing on extreme events. On the other hand, this approach does not  
332 sample climate response uncertainty, i.e., how different climate models portray  
333 the future response to greenhouse gas forcing. We discuss the value of using a  
334 large ensemble like LENS2 and how it can assist creation of higher resolution  
335 products in our Discussion. More information on these variables are in SI.B.

336 We apply a mean bias correction to LENS2 surface temperatures using  
337 surface temperatures from the ERA5 reanalysis data [63, 64]. To bias cor-  
338 rect runoff for forecasting hydroelectric generation, we use a mean bias scaling  
339 method for each of the constituent drought regions [ref B.3]. More details on  
340 the bias correction methods are in SI.B.1. Other studies using large ensem-  
341 bles for quantifying climate impacts have also used such mean bias correction  
342 methods [39]. We do not use more sophisticated bias correction methods like  
343 quantile mapping (QM) as it fits the distribution of projections to observations  
344 (historical climate), which may lead to loss of changes in internal variability  
345 in the projections. We do not find a strong bias in solar radiation, so we did  
346 not bias correct it. Though we identify biases in 10 m wind speeds relative to  
347 ERA5, wind power capacity factors derived from bias corrected wind speeds  
348 are much lower compared to other observational datasets. As a result, we use  
349 the native LENS2 wind speed data in our analysis.

350 We use different models to derive power system variables from LENS2  
351 data. We calculate daily solar and wind capacity factors for each LENS2 grid  
352 cell using deterministic equations (SI.B.2). We calculate monthly hydroelectric  
353 generation using a linear regression model using surface runoff as the predic-  
354 tor variable. We obtain the model for each drought region in the Western US  
355 [65] by training observed hydroelectric generation [66] trained against ERA5  
356 surface runoff. We then forecast hydroelectric generation using bias corrected  
357 surface runoff from the LENS2 data (SI.B.3). We calculate demand for each  
358 of our five subregions using a piecewise linear regression model using daily  
359 temperature as the predictor variable. The regression model is trained using  
360 observed demand data and ERA5 surface temperatures, so ignores technolog-  
361 ical or population changes (SI.C). We calculate temperature-dependent forced  
362 outage rates for thermal power plants using plant-type-specific relationships  
363 [67] (SI.D). We also calculate capacity deratings of fossil-based thermal power  
364 plants for each LENS2 grid cell using plant-type-specific relationships between  
365 deratings and air temperatures, relative humidity, and/or air pressure (SI.D).

366  
367  
368

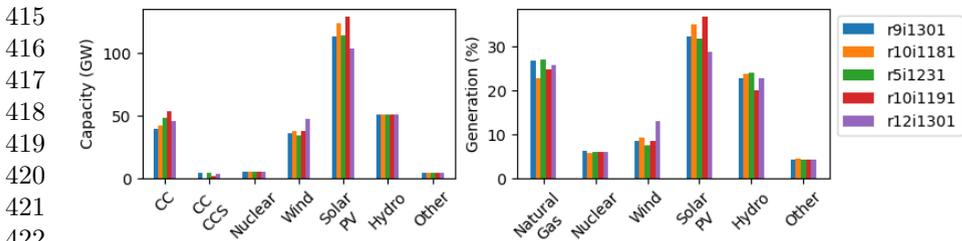

### 3 Results 369

#### 3.1 Capacity Investments across Decarbonization Pathways 370

We first examine the five decarbonization pathways output by our capacity expansion model. In creating these pathways using five sampled LENS2 ensemble members rather than creating 100 pathways using each of the 100 LENS2 ensemble members, we demonstrate the value of our framework in analyzing a limited number of alternatives generated by computationally complex planning models, similar to how alternatives are incorporated in system planning in practice. Each pathway is defined by its "fleet" of energy generator types. Our pathways decarbonize primarily through investment in wind and solar capacity, but exhibit different levels of investment (Figure 2). Interconnect-wide solar and wind capacity increase from roughly 40 and 30 GW in 2022, respectively, to up to 129 and 46 GW in 2040, respectively, across pathways. Between pathways, wind and solar capacities in 2040 range from 34 to 46 GW and from 103 to 129 GW, respectively. Small amounts (less than 4 GW) of NGCC with carbon capture and sequestration (CCS) are also deployed in four decarbonization pathways. Heterogeneity in solar and natural gas capacity largely drives differences in total installed capacity between pathways, which ranges from 252 to 280 GW. Solar capacity investment largely occurs in three regions - California, Desert Southwest, and Central - with high quality solar resources, while wind investment largely occurs in the Northwest, which has high quality wind resources (Figure A.1). No investment in interregional transmission beyond existing capacity occurs. Growth in wind, solar, and NGCC capacity displace other capacity, including coal-fired capacity, and replace lost capacity from the retirement of the Diablo Canyon nuclear generating station. Generation by plant type follows similar trends as capacity investments. Across pathways, wind, solar, natural gas, and hydropower account for roughly 7-13%, 31-37%, 23-27%, and 20-24% of annual generation, respectively, in 2040.

#### 3.2 Resource Adequacy of Decarbonization Pathways under Future Climate Realizations 401

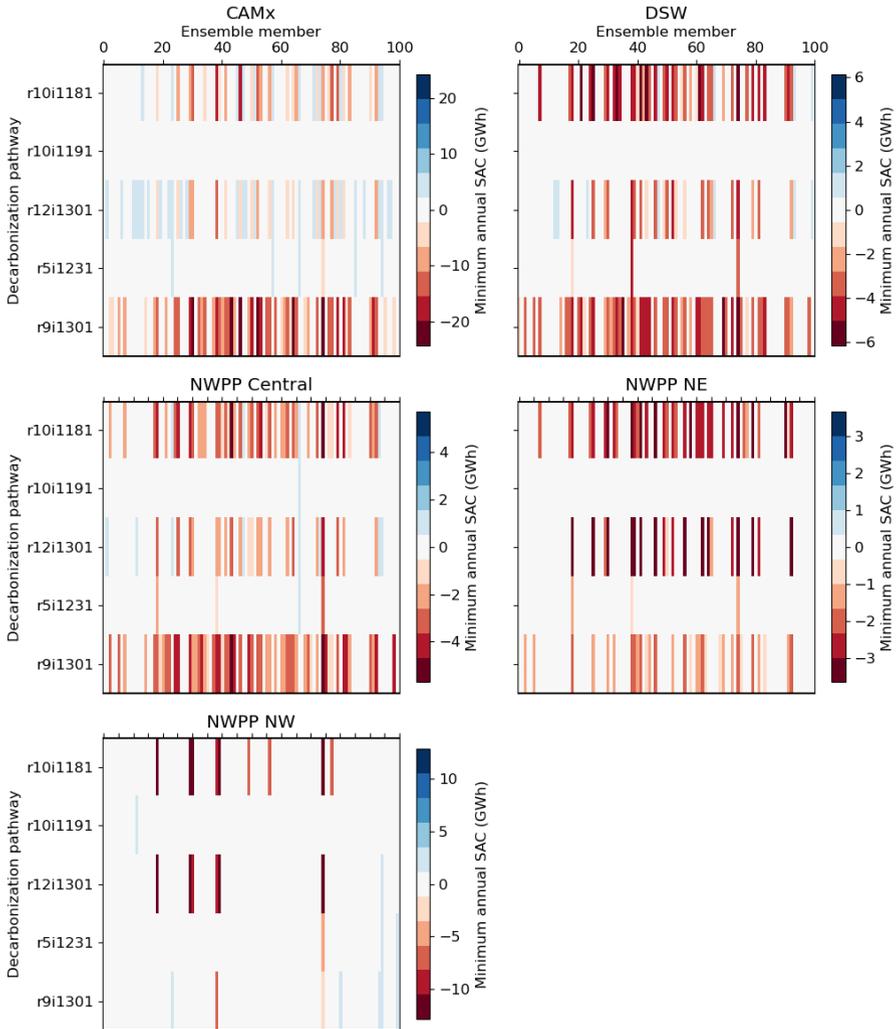

For each decarbonization pathway, we use LENS2 to quantify daily electricity supply and demand under 100 potential climate realizations in any given year. Using daily supply and demand, we approximate resource adequacy through two metrics: daily surplus available capacity (SAC) and daily energy not served (ENS), both quantified in units of electricity. SAC indicates excess electricity supply available in a region to satisfy unexpected increases in demand, while ENS equals the difference between electricity demand and supply. A negative daily SAC value indicates ENS occurs, while larger positive SAC values indicate greater redundancy against supply shortfalls. Given daily SAC and ENS for each of our five decarbonization pathways under each of our 100 ensemble members, we then calculate the annual minimum SAC ("minimum SAC"),

**Fig. 2:** (a) Installed capacity and (b) electricity generation by generator type across Western Interconnect in 2040 for each decarbonization pathway, which are labeled by the LENS2 ensemble member used to drive the capacity expansion model (detailed in Section 4.2). CC stands for natural gas combined cycle, CCCS for CC with carbon capture and sequestration, and PV for photovoltaic.

which indicates the fleet's largest susceptibility to supply shortfalls in a given year, and total annual ENS ("total ENS"), which indicates the fleet's total supply shortfall in a given year.

Figures 3 and A.2 show these two metrics for our three largest regions by demand (California, Desert Southwest, and Northwest) and the Western Interconnect in 2040. Depending on the region, resource adequacy failures occur in most or all decarbonization pathways under many climate realizations, as indicated by negative SAC values and positive total ENS values. Pathways exhibit significant differences in resource adequacy under future climate realizations. For instance, in California in 2040, one decarbonization pathway ("r9i1301", or the pathway generated using the r9i1301 climate ensemble member) has a maximum of 286 GWh of total yearly ENS, whereas the other pathways have maximum total yearly ENS of 0-100 GWh, respectively. Across decarbonization pathways, certain climate realizations incur significantly greater ENS than others (as indicated by vertical red stripes). For instance, of the total ENS across all 2040 California pathways and all 100 climate realizations, none of that ENS occurs in 79% of climate realizations, while 50% of that ENS occurs in just 3% of climate realizations. Maximum ENS values are largely driven by days with low hydropower and coinciding low wind and solar generation (Figures A.3 - A.7).

**Fig. 3:** Minimum annual SAC values for each subregion in 2040 (see Fig. 1 for map of regions). Each panel corresponds to a realization of the lower right panel of Fig. 1. Each row corresponds to one of the five decarbonization pathways, labeled by the sampled ensemble member used in the capacity expansion model to create the pathway. Within each row, there are 100 separate color bars that indicate that pathway's minimum annual SAC against each of our 100 climate ensemble members. Minimum annual SAC values range from negative (red) to positive (blue) red values indicate supply shortfalls (or resource adequacy failures), while blue values indicate surplus capacity relative to demand.

### 507 3.3 Carbon Dioxide Emissions and Costs of 508 Decarbonization Pathways under Climate 509 Realizations 510

511 Future climate variability will affect not only the resource adequacy of future  
512 fleets, but also their CO<sub>2</sub> emissions and operational costs through changes  
513 in electricity demand; available wind, solar, and hydropower potential; and  
514 generation from dispatchable (largely fossil) plants (Figure 4). Across our  
515 decarbonization pathways, climate realizations could result in CO<sub>2</sub> emissions  
516 higher or lower than the CO<sub>2</sub> cap by up to 28% and 27%, respectively. As with  
517 resource adequacy (Figure 3), CO<sub>2</sub> emissions from some decarbonization path-  
518 ways are less vulnerable to climate variability than others. For instance, one  
519 pathway ("r5i1231", or generated using the r5i1231 climate ensemble mem-  
520 ber) fails to meet the CO<sub>2</sub> emissions cap in 70% of climate realizations, while  
521 another pathway ("r10i1191") only fails to meet the emissions cap in 20%  
522 of realizations. Operational costs also vary across climate realizations in each  
523 pathway, from \$127 to \$146 billion. No single meteorological variable drives the  
524 observed variability in emissions and costs (Figure A.9). Rather, high emissions  
525 generally occur in climate realizations with low wind, solar, and hydropower  
526 generation and high demand.

547 wide CO<sub>2</sub> emissions as a fraction of the target CO<sub>2</sub> emissions cap (left) or  
548 interconnect-wide operational costs (right) in 2040.

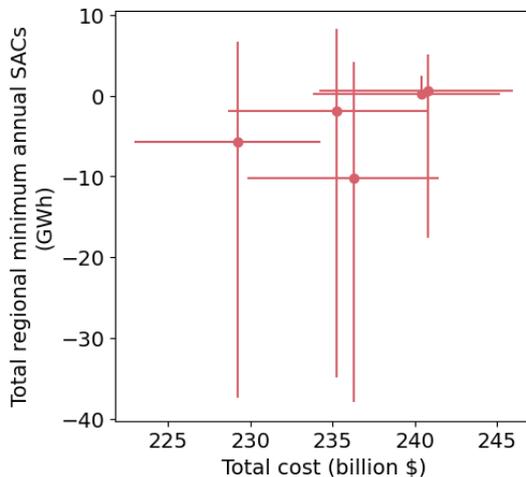

### 3.4 Trade-offs between Resource Adequacy and Costs 553

Power system planners must balance competing objectives of minimizing system costs while meeting resource adequacy targets. Figure 5 compares each decarbonization pathway’s total costs against the sum of annual minimum SAC over the five sub-regions (Figure 3) across 2040 climate realizations. Total costs include fixed investment costs, which vary between decarbonization pathways but not climate realizations, and operational costs (Figure 4), which vary between decarbonization pathways and climate realizations. Cumulative total costs from 2023 to 2040 range from \$223-246 billion across pathways and climate variability. Although pathways are differentiated by their mean costs across realizations, variability in operational costs induced by climate variability introduces overlap in total cost ranges between pathways. Despite overlaps between total costs, pathways can exhibit significant differences in resource adequacy outcomes. For instance, one pathway (“r10i1191”, or the second pathway from the right in Figure 5) only exhibits a small resource adequacy failure (or a total regional minimum annual SAC value of -0.2 GWh) under one climate realization, and has a positive mean SAC value across ensemble members. Other pathways (e.g., the three pathways at left in Figure 5) have larger resource adequacy failures (of up to -40 GWh SAC) under certain ensemble members, and negative mean SAC values across ensemble members (of up to -10 GWh). Selecting the r10i1191 pathway rather than other pathways would eliminate resource adequacy failures at a median total cost difference of -1 to 3%.

### 3.5 Identifying an Alternative Decarbonization Pathway Robust to Future Climate Realizations 578

Our prior results indicate a subset of potential climate realizations drive significant risk of resource adequacy failures across decarbonization pathways (Figure 3). We identify the ensemble member that drives the largest resource adequacy failures (quantified as the sum of minimum annual SACs) across decarbonization pathways in California (our largest load region) in 2040, namely r19i1231, then rerun our capacity expansion model using that ensemble member’s meteorology. This ensemble member was not captured in our initial sampling procedure, in which we selected five ensemble members that spanned the warming at mid-century represented by the ensembles in the CESM2-LE dataset (Figure B.10). Rather, r19i1231 features a compound extreme event in 2040 of low hydropower and wind generation potential and high air temperatures, the latter of which drive elevated electricity demand and low available thermal capacity (Figure A.10). Capturing unexpected extreme climate realizations, such as r19i1231, is a key motivator for our framework, as identifying extremes a priori is difficult given complex interactions within power systems.

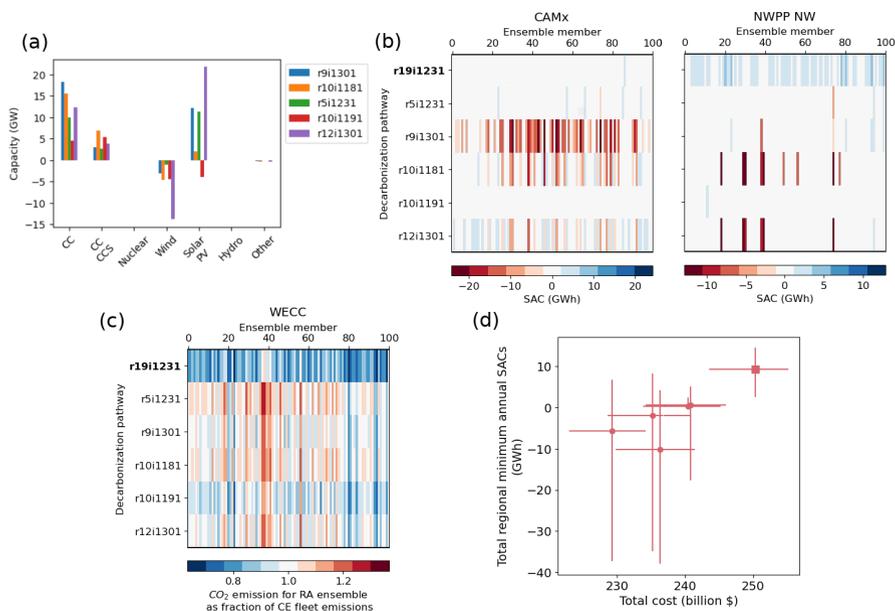

Our new decarbonization pathway generated with the r19i1231 climate ensemble member invests in more solar and NGCC capacity and in less wind capacity than other pathways (Figure 6a). Figure 6b compares the resource

**Fig. 5:** Interconnect-wide minimum annual SAC Sum of minimum annual SAC values for our five subregions in 2040 versus cumulative (2023-2040) total (fixed plus operating) costs for each decarbonization pathway. Minimum annual SAC values equal the sum of non-synchronous subregional minimum SAC values. Each decarbonization pathway is depicted with a cross; the dot at the center of each cross indicates the mean total SAC and mean total cost for that decarbonization pathway across all 100 climate ensemble members; the horizontal arm of each cross ranges from the minimum to maximum total cost for that decarbonization pathway across all 100 climate ensemble members; and the vertical arm of each cross ranges from the minimum to maximum total SACs for that decarbonization pathway across all 100 climate ensemble members. For context, total non-synchronous peak demand across the five subregions equals roughly 200 GWh (although peak demand varies across climate realizations). A negative minimum annual SAC value indicates one or more subregions in that pathway experiences a supply shortfall under at least one future climate realization.

adequacy of the decarbonization pathway generated with this new ensemble member versus our original decarbonization pathways. Our new pathway exhibits significantly higher minimum SAC values, indicating less vulnerability to resource adequacy failures. In fact, the new pathway does not experience any resource adequacy failures across any climate realizations in 2040 in any region (i.e., no ENS or negative SAC values), and has a minimum annual SAC of 0-3 GWh in California across climate realizations. The newly generated pathway also meets CO<sub>2</sub> emission caps in all but three potential climate realizations (Figure 6c). Figure 6d compares the trade-off between resource adequacy and system costs for the new versus prior pathways. The new pathway has significantly better resource adequacy than prior pathways, but at greater total costs. Specifically, the new pathway incurs, on average, roughly

\$10 billion greater total costs between 2023 and 2040 compared to the next 645  
 costliest pathway. 646

**Fig. 6:** (a) Difference in installed capacity by generator type across Western 668  
 Interconnect in 2040 between the decarbonization pathway generated using the 669  
 r19i1231 ensemble member and each of the other driving ensemble members. 670  
 CC stands for natural gas combined cycle, CCCCS for CC with carbon capture 671  
 and sequestration, and PV for photovoltaic. (b) Same structure as Figure 3, 672  
 but includes the decarbonization pathway generated using the r19i1231 ensemble 673  
 member (bolded at top) and only includes the two largest subregions by 674  
 demand for conciseness. (c) Same structure as left panel of Figure 3.3, but 675  
 includes the decarbonization pathway generated using the r19i1231 ensemble 676  
 member (bolded at top). (d) Same structure as left panel of Figure 5, but 677  
 includes the decarbonization pathway generated using the r19i1231 ensemble 678  
 member (shown as cross centered on square instead of circle). 679

## 4 Discussion 681

Existing research and system planning practices lack decision support 685  
 frameworks for identifying investment alternatives that are robust to climate-related 686  
 uncertainty. We construct such an analytical framework by integrating planning 687  
 and operational power system models with a large climate ensemble, then 688  
 use our framework to identify the vulnerabilities, trade-offs, and robustness 689  
 of alternative decarbonization pathways for the Western U.S. power system 690

691 in 2040. We began our analysis with five alternative pathways to 60% decar-  
692 bonization of the power system. All of these pathways exhibited modest to  
693 significant resource adequacy failures under potential climate realizations. But  
694 by choosing one pathway over others, significantly better resource adequacy  
695 outcomes can be achieved at little additional cost. Even this more robust  
696 pathway, though, suffered resource adequacy losses under future climate real-  
697 izations. By identifying a particularly problematic future climate realization  
698 for future resource adequacy and using it to create another alternative decar-  
699 bonization pathway, we identified a pathway robust to, or that experienced  
700 no resource adequacy failures under, all examined future climate realizations.  
701 This robustness is achieved through an increase of roughly \$10 billion (or 5%)  
702 in total costs, posing a trade-off to decision-makers.

703 Our analysis quantifies the resource adequacy of alternative decarboniza-  
704 tion pathways against an unprecedented range of near-term climate variability.  
705 Capturing this range of climate variability was possible through the use of the  
706 LENS2 dataset, but came at the cost of climate data with poor spatial and tem-  
707 poral resolution. Energy system modeling needs and available climate dataset  
708 characteristics are often misaligned [25], and conducting detailed downscaling  
709 of all LENS2 ensemble members is computationally prohibitive. However, our  
710 analytical framework can guide high resolution downscaling of large climate  
711 ensembles like LENS2 for energy system applications, a key need for energy  
712 system modelers. Specifically, our framework can identify ensemble members,  
713 periods of interest, and/or climate conditions that pose the greatest threat  
714 to alternative future power systems. Threatening conditions are themselves a  
715 function of investment decisions in power systems, so identifying those condi-  
716 tions for a broad range of alternatives, as our framework enables, is crucial  
717 to fully characterize vulnerabilities and robustness. In our case, one ensem-  
718 ble member (r19i1231) resulted in resource adequacy failures across nearly all  
719 studied decarbonization targets due to the compounding effects of low wind  
720 and hydropower generation potential and high air temperatures. Identified  
721 members, periods, or climate conditions of concern can be selectively down-  
722 scaled and fed back into planning or resource adequacy modeling, maximizing  
723 the value of high resolution downscaled data. This process requires bottom-up  
724 trans-disciplinary collaboration between energy system and climate modellers  
725 [25]. In using climate data with poor spatial (100 by 100 km) and tempo-  
726 ral (daily) resolution, our analysis is unable to capture the diurnal pattern of  
727 solar power, which could bias our investment decisions and resource adequacy  
728 analyses in favor of solar power.

729 Additional opportunities for extending our research exist. We do not con-  
730 sider changes in demand due to adoption of new technologies, e.g. heat pumps  
731 to electrify space heating or space cooling in response to increasing tempera-  
732 tures. In winter peaking regions like the Northwest, electrified heating through  
733 heat pumps can lead to higher demand in the winter months, introducing  
734 interactions between decarbonization and climate change that could affect  
735 our SAC calculations. In the Northwest and other regions with historically  
736

low space cooling penetrations, adoption of space cooling could also interact with increasing extreme heat to exacerbate summer peak demands. Incorporating the effect of such demand-side changes in our models will allow us to make accurate assessment of future fleets' robustness [9]. Future research could also extend our framework to incorporate additional robustness concepts. For instance, in practice utilities design future systems that meet certain resource adequacy thresholds, e.g. the 1-in-10 standard, which could be captured using a satisficing metric.

Our framework provides a practical way for real-world system planners and utilities to better account for climate-related uncertainty, whether planning for individual or multiple regions. Many planners and utilities use third-party software packages, e.g. PLEXOS or RESOLVE, to make long-term plans. Modifying the underlying mathematical formulation used in these packages, e.g., from a deterministic to stochastic or robust optimization, is challenging for end users. Conversely, our framework only requires changes to model inputs and additional processing of model results, a more feasible undertaking. Planners could obtain a range of climate realizations of interest, ideally in collaboration with climate scientists, then stress test their alternative plans against those climate realizations to identify system vulnerabilities and challenging climate realizations. Challenging climate realizations can then be downscaled and used in more detailed analyses, saving time and effort when compared to downscaling all realizations. Planners could further feed generated insights back into their pipeline, as we demonstrated above, to identify potentially more robust investment plans. Regulators could also require utilities to engage in stress testing during Integrated Resource Plan (IRP) proceedings to understand trade-offs between improved resource adequacy and greater consumer costs. Through practical applications like these, our framework can help practitioners identify future power systems that are robust to climate change and that simultaneously advance reliable, affordable, and clean objectives.

**Fig. A.7:** Same as figure A.3 but for NWPP Central subregion.

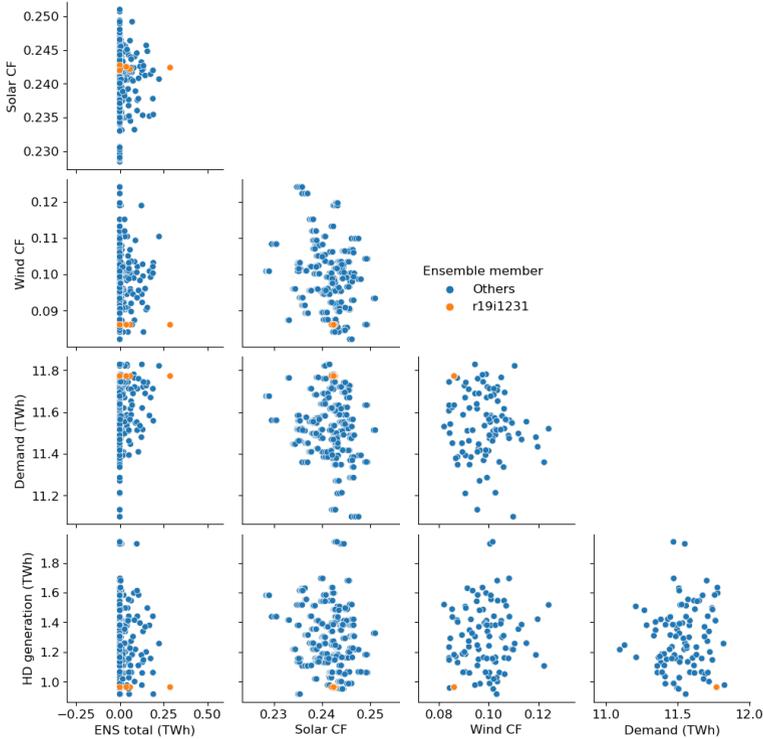

**Fig. A.8:** For our five initial decarbonization pathways evaluated against all ensemble members for the whole WECC region, this shows pair plots of weather-driven energy system variables: annual average solar capacity factors (CFs), annual average wind CFs, total annual demand, and total annual hydroelectric generation. Points are colored by annual CO<sub>2</sub> emission fractions normalized against the 40% emissions target. Emissions tend to exceed the intended cap in ensemble members with low hydropower generation and coinciding low wind and solar resources.

**Fig. A.9:** Same as figure 5 but the y-axis represents resource adequacy outcomes for each individual region.

**Fig. A.10:** Pair plots of weather-driven energy system variables in the five initial decarbonization pathways. Variables are annual average solar and wind capacity factors, total annual daily demand, total annual daily hydroelectric generation, and total annual energy not served. Data is shown for California only, the largest demand region. Yellow dots show outcomes when each pathway is run under the r19i1231p1f2 ensemble member, while blue dots show outcomes while each pathway is run under each of the other 99 ensemble members, thereby illustrating differences between r19i1231p1f2 and other members (high demand, low hydropower, and low wind).

## 1685 B.1 Bias Correction

### 1686 B.1.1 Surface Temperature

- 1688 1. Get ensemble mean temperature mean over geography of interest
- 1689 2. Compare with mean of ERA5 temperature regridded to the LENS2 grid
- 1690 over same geography
- 1691 3. Calculate bias correction factor as  $\delta_T = \overline{y_f} - \overline{y_{ra}}$
- 1692 4. Calculate bias corrected temperature as  $y_{f,corr} = y_f - \delta_T$

1710 **Fig. B.1:** Comparison of LENS2 ensemble mean temperature and ERA5 tem-  
 1711 perature for different methods of averaging.

1713

1714

## 1715 B.2 Capacity factors

1716 We derive solar capacity factors from surface downwelling shortwave flux data  
 1717 for a EFG-Polycrystalline silicon photovoltaic module using the formulation  
 1718 described by Jerez et. al. [69] [See SI section 1.1]. We calculate wind capacity  
 1719 factors from the 10m wind speed date using the formulation described by  
 1720 Karnauskas et. al. [19] and the composite 1.5 MW IEC class III turbine from  
 1721 the System Advisor Model [70].  
 1722

1723

### 1724 B.2.1 Solar

1725 We derive daily solar capacity factors for a EFG-Polycrystalline silicon  
 1726 photovoltaic module as[? ]:

1727

1728

1729

1730

$$CF_{pv}^t = P_R^t \frac{FSDS^d}{RSDS_{STC}} \quad (1)$$

where  $RSDS^d$  represents surface downwelling shortwave flux in air [ $Wm^{-2}$ ] where the superscript  $d$  indexes the day. All the meteorological variables are discrete in time and space (at the dataset resolution), and the index  $d$  is dropped hereafter for conciseness. In eq.1,  $RSDS_{STC}$  refers to FS<sub>SDS</sub> at standard test conditions and is equal to  $1000Wm^{-2}$ , and  $P_R^t$  is the performance ratio calculated using

$$P_R = 1 + \gamma[T_{cell} - T_{STC}] \quad (2)$$

$$T_{cell} = c_1 + c_2TREFHT + c_3FS_{SDS} + c_4SWS \quad (3)$$

where  $T_{cell}$  is the PV cell temperature, TAS is surface air temperature ( $2m$  temperature) and SWS is surface wind speed. In eq.2,  $\gamma = -0.005^\circ C^{-1}$  and  $T_{STC} = 25^\circ C$ . In eq.3,  $c_1 = 4.3^\circ C$ ,  $c_2 = 0.943$ ,  $c_3 = 0.028^\circ C m^2 W^{-1}$ , and  $c_4 = -1.528^\circ C sm^{-1}$  [71].

### B.2.2 Wind

We calculate wind capacity factors using the formulation described in [19] for the composite 1.5 MW IEC class III turbine with power curves from the System Advisor Model (SAM) [70] as:

$$CF_{wind}^d = p(W_{100}^d) \quad (4)$$

where  $p$  is a function describing the power curve and  $W_{100}^d$  is the daily corrected 100m wind speed. The correction accounts for air density and humidity related effects on the wind turbine performance and is carried out as:

$$W_{100} = W_{10} \left( \frac{100m}{10m} \right)^{1/7} \quad (5)$$

$$W_{100} = W_{100} \left( \frac{\rho_m}{1.225} \right)^{1/3} \quad (6)$$

$$\rho_m = \rho_d \left( \frac{1 + QREFHT}{1 + 1.609 \times HUSS} \right) \quad (7)$$

$$\rho_d = \frac{PS}{\mathbf{R} \times (T + 273.15)} \quad (8)$$

Eqs.5 and 6 scales the 10m wind speed to 100m and correct for air density as this affects the force exerted on the turbine blades, where  $\rho_m$  is the humidity corrected air density, which is in turn derived from the surface specific humidity ( $HUSS$ ) as shown in eq.7.  $\rho_d$  is the dry air density which is derived using the ideal gas law from surface pressure [units-Pa] ( $PS$ ) and surface temperature ( $T$ ) as shown in eq.8, where  $\mathbf{R} = 287.058 Jkg^{-1}K^{-1}$  is the gas constant.

We estimate wind generation for all locations across WECC assuming a class-III wind turbine. The power curve from SAM is provided as the power

1777 output at discrete wind speeds (figure B.2), and we convert this into a con-  
 1778 tinuous function through linear interpolation. We include the discrete power  
 1779 curve in this SI.

### 1799 B.3 Hydroelectricity generation

1800 We obtain monthly hydroelectric generation forecasts using a linear regres-  
 1801 sion model which predicts hydro electric generation as a function of runoff.  
 1802 We train the regression against cleaned plant level hydroelectric generation  
 1803 from the RectifHyd dataset [66] and river run-off from the ERA5-land dataset.  
 1804 To predict the hydro generation for each ensemble member we use the runoff  
 1805 data from the LENS2 dataset. Owing to the coarse resolution of the LENS2  
 1806 data, and computational costs to obtain river run and reservoir flows, we build  
 1807 our regression models for individual "drought regions". These drought regions  
 1808 represent eight hydropower climatic regions for the western US, and deter-  
 1809 mined using clustering techniques based on similarity of climatic conditions  
 1810 and reservoir characteristics [65].

1811 We carry out the hydroelectric generation forecasting with the following  
 1812 steps:

1813

- 1814 1. ERA5 representation of runoff is daily accumulations at 00 hours in m/day  
 1815 and averaged over month, cesm is daily mean at mm/day averaged over  
 1816 month, so we reconcile these to the same units.
- 1817 2. There is a bias between LENS2 and ERA5-Land datasets, so we bias cor-  
 1818 rect LENS2 data ensemble mean to match reanalysis data for the period  
 1819 1980-2020 using a scaling factor. Figure B.6 shows the bias correction factors  
 1820 for each drought region. The range in the figure represents the bias  
 1821 correction factors if we corrected each ensemble member individually rather  
 1822 than correcting the ensemble mean.

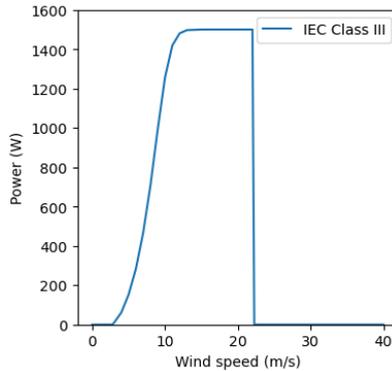

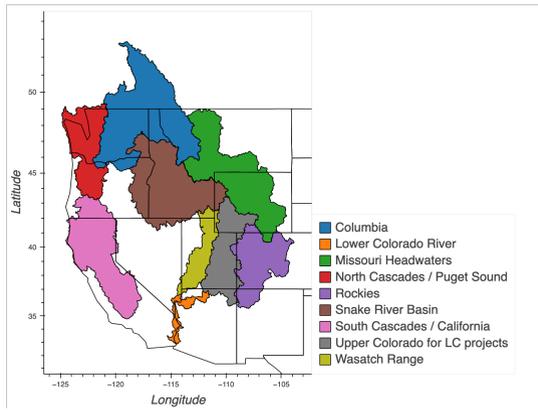

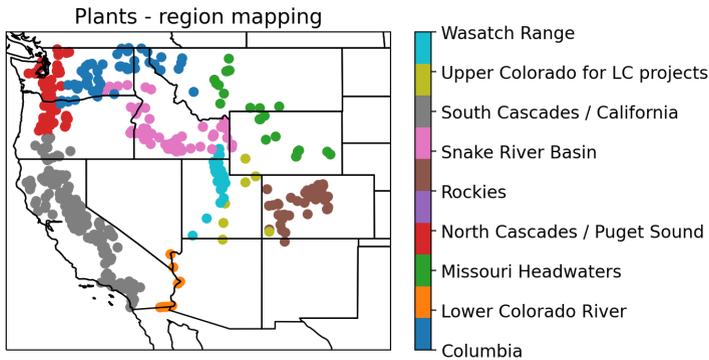

Fig. B.2: Power curve for 1.5 MW IEC class III turbine

3. We then train our regression models to predict annual generation (for a hydrological year), using the observed hydro generation data and ERA5 surface run off. We predict annual generation based on LENS2 data and use the monthly shapes in figure B.7 to get monthly generation.
4. Figures B.8 and B.9 show predicted hydroelectric generation from all ensembles at the drought regional level and from 1 ensemble for the WECC subregions respectively.

## C Demand Forecasting

We derive daily subregional demand for each ensemble member using a piecewise linear regression (PLR) model [15]. The model predicts daily demand from subregional averaged daily surface temperature. We train the model with daily demand data, which is obtained by processing observed demand [72], and observed daily temperatures from ERA5. In the regression formulation we include fixed effects based on day of the week and the season. We obtain temperature bins to apply the piecewise model by splitting the subregional temperatures into 6 bins containing same number of datapoints. Because the subregions experience different temperature, we have different bins for each subregion.

### C.1 Regional Demand for Electricity

The sub-regional loads are constructed by aggregating loads in smaller balancing authorities located within their boundaries [Table 3].

Subregion	Temperature Bins (°C)					
	Segment 1	Segment 2	Segment 3	Segment 4	Segment 5	Segment 6

## 2219 **D Capacity Deratings and** 2220 **Temperature-Dependent Forced Outage** 2221 **Rates of Fossil-Based Thermal Power Plants** 2222

2223 Fossil-based thermal power plants are vulnerable to capacity deratings, or  
2224 reductions in available generating capacity. We estimate deratings using exist-  
2225 ing bottom-up relationships for steam turbine and combined cycle (CC) plants  
2226 with recirculating or dry cooling and for combustion turbines. Deratings for  
2227 plants with once through cooling are driven by water intake conditions (e.g.,  
2228 river temperatures) and regulations, so requires detailed hydrological model-  
2229 ing outside of our analytic scope. We approximate deratings of coal and CC  
2230 facilities with carbon capture and sequestration (CCS) to be the same as coal  
2231 and CC facilities without CCS. Deratings are calculated following the methods  
2232 following Craig et al. (2020), which sources a bottom-up derating estimate for  
2233 combustion turbines from Bartos and Chester (2015) and a statistical model  
2234 of deratings at coal and gas STs and CCs from Loew et al. (2018). In these  
2235 relationships, CT deratings are a function of surface air temperatures; STs and  
2236 CCs with recirculating cooling (RC) are a function of surface air temperatures  
2237 and relative humidity; and STs and CCs with dry cooling (DC) are a function  
2238 of surface air temperatures and surface air pressure. RC and DC facilities have  
2239 varying designs, which in turn have varying vulnerabilities to thermal derat-  
2240 ings. Data on RC and DC designs is not publicly available, so we assume RC  
2241 and DC designs that are moderately resilient against deratings. Specifically,  
2242 we assume a RC design of inlet and outlet cooling water temperatures of 75  
2243 and 95 degrees F, respectively, and a DC design with an initial temperature  
2244 difference of 45 degrees F. We obtain cooling types by power plant from EIA  
2245 Form 860.

2246 We calculate temperature-dependent forced outage rates for thermal power  
2247 plants using the best available plant-type-specific relationships from existing  
2248 literature [67].

## 2293 **E Capacity Expansion Model**

2294 The capacity expansion (CE) model optimizes new capacity investments, oper-  
2295 ations of new and existing units, and inter-regional electricity transfers by  
2296 minimizing total system costs subject to system and unit-level constraints.  
2297 Total system costs equal the sum of the cost of electricity generation of existing  
2298 and new units and the cost of new capacity investments. Electricity genera-  
2299 tion costs equal the sum of fixed operations and maintenance (O&M) costs  
2300 and variable electricity generation costs, which include fuel costs and variable  
2301 O&M costs. The model runs from 2023 to 2040 in 2-year time steps. In each  
2302 model run, the CE model can build natural gas combined cycle (NGCC), wind,  
2303 and solar generators, and can build coal or NGCC with carbon capture and  
2304 sequestration (CCS) beginning in 2031 given the current immature state of  
2305 the technology. We obtain overnight capital costs and fixed and variable oper-  
2306 ation and maintenance (O&M) costs for each time step from NREL's Annual  
2307 Technology Baseline (ATB) moderate technology development scenario [73].

2308 The CEM model divides WECC into five regions; inter-regional transmis-  
2309 sion and capacity investments are optimized between regions, and supply and  
2310 demand are balanced within each region (accounting for imports and exports).

2311 To reflect ongoing scale up of wind and solar investment potential, we  
2312 include a WECC-wide limit on wind and solar investments in each time step.  
2313 Annual limits begin in the first model run (2023-2024) at 5.2 and 6.8 GW for  
2314 wind and solar, respectively, or double the maximum annual capacity addi-  
2315 tions in recent years (2020-2022) since our model runs in 2-year time steps.  
2316 Maximum potential wind and solar investments grow through 2040 at a com-  
2317 pounding annual growth rate of 0.3. In addition to WECC-wide investment  
2318 limits on wind and solar, we capture local limits on capacity investments  
2319 following methods outlined by Wu et al. [74]. In general, we exclude devel-  
2320 opable area on the basis of environmental, techno-economic, land use, and legal  
2321 criteria. Exclusions include Bureau of Land Management (BLM) exclusions;  
2322 United States Geologic Service protected areas; airports; lakes; mines; military  
2323 areas; census urban zones; flood zones; high slopes; and high population den-  
2324 sities. After accounting for exclusions, we sum available area for wind or solar  
2325 deployment by CESM2 grid cell, convert area to installed capacity using wind  
2326 and solar densities of 0.9 and 5.7 W per square meter [75], respectively, and  
2327 optimize wind and solar investments at the grid cell level.

2332

2333

2334

2335

2336

2337

2338

Parameter	Definition	Unit
$P_i^{MAX}$	Maximum power rating of existing unit $i$	MW
$P_c^{MAX}$	Maximum power rating of new unit $c$	MW
$P_l^{MAX}$	Maximum transmission capacity of line $l$	MW
$FOM_c$	Fixed O&M cost of new unit $c$	\$/MW/year
$OCC_c$	Overnight capital cost of new unit $c$	\$/MW
$OCC_l$	Overnight capital cost of transmission expansion along line $l$	\$/MW
$CRF_c$	Capital recovery factor of new unit $c$	\$/MW
$CRF_l$	Capital recovery factor of new transmission line $l$	\$/MW
$OC_c$	Operational cost of new unit $c$	\$/MW
$VOM_c$	Variable O&M cost of new unit $c$	\$/MW
$VOM_i$	Variable O&M cost of existing unit $i$	\$/MW
$OC_i$	Operational cost of existing unit $i$	\$/MW
$OC_c$	Operational cost of new unit $c$	\$/MW
$FC_c$	Fuel cost of new unit $c$	\$/MMBtu
$FC_i$	Fuel cost of existing unit $i$	\$/MMBtu
$HR_c$	Heat rate of new unit $c$	MMBtu/MWh
$HR_i$	Heat rate of existing unit $i$	MMBtu/MWh
$ER_i^{CO_2}$	CO <sub>2</sub> emissions rate of existing unit $i$	ton/MMBtu
$ER_c^{CO_2}$	CO <sub>2</sub> emissions rate of new unit $c$	ton/MMBtu
$R$	Discount rate = 0.07	-
$LT_c$	Life time of new units $c$	Years
$N_{cr}^{MAX}$	Maximum capacity of new wind or solar units $c$ built	MW
$P_{cr}^{WECC,MAX}$	Maximum number of total renewable capacity $c_r$ built WECC-wide	MW
$D_{z,t}$	Total load (or electricity demand) in region $z$ at time $t$	MW
$D_t$	Total load (or electricity demand) across regions at time $t$	MW

Table 7: List of Parameters

Parameter	Definition	Unit
$P_{t,z}^{MAX,WIND}$	Maximum aggregate wind profile in region $z$ at time $t$	MW
$P_{t,z}^{MAX,SOLAR}$	Maximum aggregate solar profile in region $z$ at time $t$	MW
$H_{b,z}$	Maximum hydropower generation in region $z$ and month $b$	MW
$FOR_{i,t}$	Forced outage rate of existing unit $i$ at time $t$	-
$DR_{i_{th},t}$	Capacity derate of existing thermal CT, CC, or coal plants $i_{th}$ at time $t$	-
$DR_{c_{th},t}$	Capacity derate of new thermal CC or coal plants $c_{th}$ at time $t$	-
$FOR_t^{RE}$	Forced outage rate of existing wind and solar units at time $t$	-
$FOR_{c,t}$	Forced outage rate of new unit $c$ at time $t$	-
$E_{CO_2}^{MAX}$	WECC-wide carbon dioxide emissions cap	tons
$CF_{c_r,t}$	Capacity factor of new renewable unit $c_r$ at time $t$	-
$RL_i$	Maximum ramp rate of existing unit $i$	MW
$RL_c$	Maximum ramp rate of new unit $c$	MW
$\nu$	Transmission losses per unit of electricity transferred between regions	%

Table 9: List of Variables

## 2419 E.2 Objective Function

2420 The CE model's objective function minimizes total annual fixed plus variable  
 2421 costs, where fixed costs capture investment costs in new transmission and  
 2422 electricity generators, and variable costs capture operational costs of new and  
 2423 existing generators:  
 2424

$$\begin{aligned}
 2425 \quad TC^{CE} = & \left[ \sum_c n_c \times P_c^{MAX} \times (FOM_c + OCC_c \times CRF_c) \right] \\
 2426 & + \left[ \sum_l n_l \times OCC_l \times CRF_l \right] + \left[ \sum_t \left( \sum_c p_{c,t} \times OC_c + \sum_i p_{i,t} \times OC_i \right) \right], \\
 2427 & \\
 2428 & \\
 2429 & \\
 2430 &
 \end{aligned}$$

$$\forall i \in \mathbb{I}, c \in \mathbb{C}, l \in \mathbb{L} \quad (9) \quad 2431$$

where  $c$  indexes potential new units;  $t$  indexes time intervals (days);  $i$  indexes existing units;  $l$  indexes potential new transmission lines;  $n_c$  is number of new unit investments;  $n_l$  is total new transmission line capacity investments in line  $l$  (MW);  $P^{MAX}$  is maximum capacity of unit (MW);  $FOM$  is fixed operation and maintenance (O&M) costs of units (\$/MW/year);  $OCC$  is overnight capital cost of new investments (\$/MW);  $CRF$  is capital recovery factor;  $p_c$  is electricity generation from new unit  $c$  (MWh);  $p_i$  is electricity generation from existing unit  $i$  (MWh); and  $OC$  is operational costs of new or existing units (\$/MWh).  $OC$  is defined for new and existing generators as:

$$OC_i = VOM_i + HR_i \times FC_i \quad \forall i \in \mathbb{I}, \quad (10a) \quad 2443$$

$$OC_c = VOM_c + HR_c \times FC_c \quad \forall c \in \mathbb{C} \quad (10b) \quad 2444$$

where  $VOM$  is variable O&M costs (\$/MWh),  $HR$  is heat rate (MMBtu/MWh), and  $FC$  is fuel cost (\$/MMBtu).  $CRF_c$  is defined as:

$$CRF_c = \frac{R}{1 - \frac{1}{(1+R)^{LT_c}}} \quad \forall c \in \mathbb{C}, \quad (11) \quad 2450$$

where  $R$  is discount rate and  $LT$  is plant lifetime (years).

### E.3 System-level Constraints

The CE model requires total adjusted capacity to meet peak annual demand on a WECC-wide basis:

$$\begin{aligned} D_t \leq & \sum_{c_{th} \in C_{th}} P_{c_{th}}^{MAX} \times (1 - FOR_{c_{th},t}) \times (1 - DR_{c_{th},t}) \times n_{c_{th}} \\ & + \sum_{c_r \in C_r} P_{c_r}^{MAX} \times (1 - FOR_{c_r,t}) \times n_{c_r} \times CF_{c_r,t} \\ & + \sum_{i \in (I - I_w - I_o - I_{TH})} (1 - FOR_{i,t}) \times P_i^{MAX} \\ & + \sum_{i_{th} \in I_{TH}} (1 - FOR_{i_{th},t}) \times (1 - DR_{i_{th},t}) \times P_{i_{th}}^{MAX} \\ & + \sum_z (P_{z,t}^{MAX,SOLAR} + P_{z,t}^{MAX,WIND}) \times (1 - FOR_t^{RE}), \\ & \forall t \in \mathbb{T}_p \end{aligned} \quad (12) \quad 2461$$

where  $c_{th}$  and  $c_r$  index new thermal and renewable plant types, respectively;  $i_w$  and  $i_o$  index existing wind and solar generators, respectively;

2477  $z$  indexes regions;  $FOR$  is forced outage rate;  $CF$  is capacity factor;  
 2478  $P^{MAX,SOLAR}$  is maximum regional generation by existing solar generators  
 2479 (MWh);  $P^{MAX,WIND}$  is maximum regional generation by existing wind gener-  
 2480 ators (MWh); and  $T_p$  indicates the annual peak demand day. Adjusted capacity  
 2481 here accounts for temperature-dependent forced outage rates of generators  
 2482 [Table 6] and daily capacity factors for wind and solar facilities. Note that this  
 2483 PRM is enforced across all of WECC rather than on a region-by-region basis.

2484 The CE model also requires supply balance demand at each time step:

$$2485$$

$$2486$$

$$2487 D_{z,t} + \sum_{l_z^{OUT} \in \mathbb{L}_z^{OUT}} f_{l_z^{OUT},t} \leq \sum_{i_z \in \mathbb{I}_z} p_{i_z,t} + \sum_{c_z \in \mathbb{C}_z} p_{c_z,t}$$

$$2488 + \sum_{l_z^{IN} \in \mathbb{L}_z^{IN}} f_{l_z^{IN},t} \times \nu, \quad \forall z \in \mathbb{Z}, t \in \mathbb{T}, \quad (13)$$

$$2489$$

$$2490$$

$$2491$$

2492 where  $z$  indexes zones,  $l$  indexes transmission lines,  $i_z$  indexes existing units  
 2493 in region  $z$ ,  $c_z$  indexes new units in region  $z$ ,  $l_z^{IN}$  indexes lines flowing out of  
 2494 region  $z$ ,  $l_z^{OUT}$  indexes transmission lines flowing out of region  $z$ ,  $\nu$  indicates  
 2495 losses for each unit of electricity imported into a region (assumed to be 5%),  
 2496 and  $f$  is electricity flows along transmission lines.

2497 The total electricity flow through a transmission line ( $f_{l,t}$ ) cannot exceed  
 2498 the line's initial transmission capacity ( $P_l^{MAX}$ ) plus new capacity investments  
 2499 ( $n_l$ ):

$$2500$$

$$2501 f_{l,t} \leq P_l^{MAX} + n_l, \quad \forall l \in \mathbb{L}, t \in \mathbb{T}, \quad (14)$$

$$2502$$

2503 where  $l$  indexes transmission lines, and  $f_{l,t}$  is total electricity flow in line  $l$  at  
 2504 time  $t$  (MWh).

2506 To examine power systems that meet alternative decarbonization targets,  
 2507 we enforce four different CO<sub>2</sub> emission caps ( $E_{CO_2}^{MAX}$  on WECC-wide emissions:

$$2508$$

$$2509 E_{CO_2}^{MAX} \geq \left[ \sum_t \left( \sum_i p_{i,t} \times HR_i \times ER_i^{CO_2} + \sum_c p_{c,t} \times HR_c \times ER_c^{CO_2} \right) \right],$$

$$2510$$

$$2511 \forall t \in \mathbb{T}, \forall i \in \mathbb{I}, \forall c \in \mathbb{C} \quad (15)$$

$$2512$$

$$2513$$

2514 where  $ER^{CO_2}$  is CO<sub>2</sub> emission rate (ton/MMBtu).

2515 As detailed above, we enforce a WECC-wide cap on wind and solar  
 2516 investments ( $P_{c_r}^{WECC,MAX}$ ) (MW) to reflect scaling up of both industries:

$$2517$$

$$2518 \sum_{c_r} n_{c_r} \times P_{c_r}^{MAX} \leq P_{c_r}^{WECC,MAX}, \quad \forall c_r \in \mathbb{C}_r \quad (16)$$

$$2519$$

$$2520$$

$$2521$$

2522 where  $n_{c_r}$  equals investment in new wind or solar plants.

## E.4 Unit-level Constraints

### E.4.1 Investment constraints

As explained above, the CE model places an upper bound on wind and solar investments by grid cell based on the area of each grid cell; restrictions on development based on technoeconomic, legal, environmental, and land-use criteria; and the energy density of wind and solar:

$$0 \leq n_{c_r} \times P_{c_r}^{MAX} \leq N_{c_r}^{MAX}, \quad \forall c_r \in \mathbb{C}_r \quad (17)$$

where  $n_{c_r}$  equals investment in new wind or solar plants and  $N_{c_r}^{MAX}$  equals the maximum investment in new wind or solar plants by grid cell. Existing wind and solar capacities are subtracted from the grid cell's maximum capacity in calculating  $N_{c_r}^{MAX}$ .

### E.4.2 Generation constraints

For existing generators, electricity generation is limited by the generators' capacities:

$$0 \leq p_{i,t} \leq P_i^{MAX}, \quad \forall t \in \mathbb{T}, i \in \mathbb{I} \quad (18)$$

Thermal plants are vulnerable to deratings at certain ambient air temperatures. We account for deratings of combustion turbines, NGCCs, and coal-fired power plants across space and time (Section SI.D) and limit their daily generation to their derated capacity as follows:

$$p_{i_{th},t} \leq DR_{i_{th},t} \times P_{i_{th}}^{MAX}, \quad \forall t \in \mathbb{T}, i_{th} \in \mathbb{I}_{\approx} \approx p_{c_{th},t} \leq n_{c_{th}} \times DR_{c_{th},t} \times P_{c_{th}}^{MAX}, \quad \forall t \in \mathbb{T}, c_{th} \in \mathbb{C}_{th} \quad (19a)$$

Combined electricity generation by existing wind and solar generators is limited to aggregate wind and solar generation profiles:

$$\sum_{i_{w_z} \in \mathbb{I}_{w_z}} p_{i_{w_z},t} \leq P_{z,t}^{MAX,WIND}, \quad \forall t \in \mathbb{T}, z \in \mathbb{Z}, \quad (20a)$$

$$\sum_{i_{o_z} \in \mathbb{I}_{o_z}} p_{i_{o_z},t} \leq P_{z,t}^{MAX,SOLAR}, \quad \forall t \in \mathbb{T}, z \in \mathbb{Z}, \quad (20b)$$

New generators' electricity generation cannot exceed their new capacity investments:

$$0 \leq p_{c,t} \leq n_c \times P_c^{MAX}, \quad \forall t \in \mathbb{T}, c \in \mathbb{C} \quad (21)$$

2569 Electricity generation by new renewable generators is also constrained by  
 2570 site-specific capacity factor timeseries:

$$2571 \quad p_{c_r,t} \leq n_{c_r} \times P_{c_r}^{MAX} \times CF_{c_r,t}, \quad \forall t \in \mathbb{T}, c_r \in \mathbb{C}_r \quad (22)$$

2574 Hydropower generation is constrained based on observed data for each of  
 2575 our weather years. Since we ignore transmission constraints within each of  
 2576 our five regions, we aggregate hydropower capacity by region, then limit total  
 2577 hydropower generation by month (or time block):

$$2578 \quad \sum_{t_b \in T_b, i_{h_z} \in I_{h_z}} p_{i_{h_z}, t_b} \leq H_{b,z}, \forall z \in \mathbb{Z}, b \in \mathbb{B} \quad (23)$$

2582 where  $i_{h_z}$  indexes all hydropower units in region  $z$  and  $H_{b,z}$  equals maximum  
 2583 total hydropower generation in month  $b$  and region  $z$  [??].

2584 The CE model places an upper bound on upwards changes in electricity  
 2585 generation from one time period to the next, i.e. in upward ramps, for new  
 2586 and existing units:

$$2587 \quad p_{i,t_b} - p_{i,t_b-1} \leq RL_i, \quad \forall t_b > 1, i \in \mathbb{I} \quad (24a)$$

$$2589 \quad p_{c,t_b} - p_{c,t_b-1} \leq n_c \times P_c^{MAX} \times RL_c \quad \forall t_b > 1, c \in \mathbb{C} \quad (24b)$$

2591 where  $RL$  equals the ramp limit. We only constrain upwards ramps for two  
 2592 reasons: (1) downward ramps can be more easily achieved through curtailment  
 2593 of renewables than upwards ramps and (2) for computational tractability.

## 2595 E.5 Data

2597 In this section, we discuss the data and intermediate steps to calculate the  
 2598 parameters that are used in the model.

### 2600 E.5.1 Regional Demand for Electricity

2602 The sub-regional loads are constructed by aggregating loads in smaller  
 2603 balancing authorities located within their boundaries per the following table.

### 2605 E.5.2 Generator Fleet

#### 2606 *Initial Generator Fleet*

2608 To construct our 2022 initial representative existing generator fleet, we begin  
 2609 with unit-level data on active existing units from *The National Electric Energy*  
 2610 *Data System* (NEEDS) dataset version 6 (updated in February 2023) [? ].  
 2611 Because NEEDS lacks several parameters needed in our CE model, we merge  
 2612 the NEEDS dataset with EIA860 dataset [? ] and add carbon dioxide (CO<sub>2</sub>)  
 2613 emission rates from the the U.S. Energy Information Administration (EIA)'s  
 2614 *Carbon Dioxide Emissions Coefficients* [? ], fuel prices from EIA's *Annual*

Sub-region	CC gas	OC gas	Hydro	Nuclear	Coal	Solar	Wind	Other
CAMX	20641	10825	10147	0	17	10644	5764	4010
Desert Southwest	11256	4855	3840	3937	5333	2303	1488	363
NWPP Central	10486	5053	954	0	6693	3128	3636	1045
NWPP NE	94	465	3493	0	6562	40	2906	23
NWPP NW	6619	1669	32091	1180	0	356	6568	557

**Table 10:** Initial generator fleet capacity of each generator type (in MW) across the subregions. CC indicates combined cycle; OC open cycle; and coal plants are steam turbine plants.

*Energy Outlook 2023, Table 3. Energy Prices by Sector and Source* [? ], and variable operation and maintenance (O&M) costs from [73]. We isolate generators within WECC, our study region, using shape files of balancing areas within WECC from NREL's ReEDS model [76]. Our initial generator fleet is described in the table 10. The *other* type of generators in the table below include geothermal, different types of waste, biomass, and other small fossil generators, which are all modeled as dispatchable capacity in the CEM and RAM.

### *Generator Fleet Compression*

Because the existing generation fleet in WECC is large with over 4,500 units, we combine (or aggregate) existing small generators into larger generators for computational tractability. We aggregate generators within the same region using two steps and several criteria. First, for each fuel type and plant type with zero marginal costs, we aggregate all generators into a single generator by region. Zero marginal cost generators include all geothermal, wind, solar, landfill gas, municipal solid waste, biomass, and non-fossil waste generators. Second, for each fuel type and plant type with non-zero marginal costs, we aggregate generators based on age and heat rate to preserve heterogeneity in operational costs. These non-zero marginal cost units include distillate fuel oil, natural gas combined cycle, natural gas combustion turbine, residual fuel oil, and coal (including bituminous, sub-bituminous, and lignite) generators. Specifically, by region, plant type, and fuel type, we divide generators into 4 heat rate blocks, then aggregate generators together within each heat rate block by decade between 1975 and 2026. We aggregate generators up to 200 MW in size in this manner, and create combined generators of up to 10,000 MW. These size thresholds significantly reduce the size of the generator fleet while still individually modeling mid- to large-sized power plants. Heat rates and CO<sub>2</sub> emission rates of the aggregated generators equal the capacity-weighted heat rates and CO<sub>2</sub> emission rates of their constituent generators.

	Transmission Capacity between	Total Capacity (GW)	Expansion Cost (1000\$/MW)
2661	NWPP-NW and NWPP-NE	12.3	474
2662	NWPP-NW and CAMX	7.1	1,018
2663	NWPP-NW and NWPP-Central	1.5	569
2664	NWPP-NE and NWPP-Central	6.0	431
2665	CAMX and Desert Southwest	3.0	1,070
2665	CAMX and NWPP-Central	4.6	816
2666	Desert Southwest and NWPP-Central	5.6	348

**Table 11:** Transmission Networks within WECC

**E.5.3 System Topology**

2671

2672 Our resource adequacy (RA) model uses the five regions that WECC uses  
 2673 to quantify resource adequacy in WECC [59]: NWPP NW, NWPP NE,  
 2674 CAMX, Desert Southwest, and NWPP Central [see figure E.1]. To align regions  
 2675 between the CE and RA models, we model these same five regions in our CE  
 2676 model.

2676

2677 Within each of these regions, we ignore transmission constraints. Between  
 2678 regions, we enforce transmission constraints. Given the lack of data regarding  
 2679 transmission constraints between our WECC resource adequacy regions, we  
 2680 estimate inter-regional transmission constraints using data from the National  
 2681 Renewable Energy Laboratory (NREL) Regional Energy Deployment System  
 2682 (ReEDS) model. ReEDS provides transmission constraints between 35 bal-  
 2683 ancing areas across WECC. We assign each balancing area to a region using  
 2684 spatial overlays, then set transmission constraints between each pair of regions  
 2685 as the sum of transmission constraints between each pair of balancing areas  
 2686 within each region. Using this method, we identify seven inter-regional, bi-  
 2687 directional transmission constraints. For each of these seven inter-regional  
 2688 transmission constraints, we limit daily inter-regional electricity transfers to  
 2689 an upper capacity bound.

2689

2690 In addition to enforcing existing transmission constraints, the CE model  
 2691 can also invest in new transmission capacity between each of the seven inter-  
 2692 regional transmission interfaces identified above. Similar to other macro-scale  
 2693 planning models [77], we assume costs scale linearly with new transmission  
 2694 capacity, allowing us to maintain a computationally tractable linear program  
 2695 (LP). Per-MW costs of transmission expansion equal the distance (in miles)  
 2696 between the two centroids of interconnected regions times the per MW-mile  
 2697 cost of each bi-directional transmission line. We estimate this cost as the  
 2698 median of costs between each pair of balancing authorities between regions,  
 2699 which is taken from NREL's ReEDS Model's open access github [76]. Table  
 2700 11 depicts all possible combinations of aggregate links between our five load  
 2701 regions and their respective aggregate capacities and total cost per MW.

## F Economic Dispatch Model

To calculate daily SAC and ENS, we run an economic dispatch model (EDM) for each decarbonization pathway output by our capacity expansion model in 2030 and 2040. The EDM minimizes the sum of operating, CO<sub>2</sub> emission, inter-regional transmission, and ENS costs by optimizing generation, inter-regional transmission, and ENS decision variables. Our EDM divides WECC into the same five regions as our CEM; inter-regional transmission and capacity investments are optimized between regions, and supply and demand are balanced within each region (accounting for imports and exports). For computational tractability, the EDM aggregates geothermal, waste, biomass, and other small fossil plants of small capacities within each plant type together (these plant types are denoted as *other* plant type in our results).

### F.1 Functional Forms

#### F.1.1 Parameters and Variables

#### F.2 Objective Function

The EDM model's objective function is:

$$\begin{aligned}
 TC^{EDM} = & \sum_{i,t} p_{i,t} \times (OC_i + HR_i \times ER_i^{CO_2} \times CP) + \sum_{z,t} ens_{z,t} \times CENS \\
 & + \sum_{l,t} f_{l,t} \times FLC \quad \forall i \in \mathbb{I}, l \in \mathbb{L}, z \in \mathbb{Z}
 \end{aligned} \tag{25}$$

where  $t$  indexes time intervals (days);  $i$  indexes existing units;  $l$  indexes transmission lines;  $z$  indexes regions;  $p$  is electricity generation (MWh);  $OC$  is operational cost (\$/MWh);  $HR$  is heat rate (MMBtu/MWh);  $ER$  is CO<sub>2</sub> emissions rate (ton/MMBtu);  $CP$  is CO<sub>2</sub> emissions price (\$/ton);  $ens$  is energy not served (MWh);  $CENS$  is cost of energy not served (\$/MWh);  $FLC$  is the

2786	$\mathbb{T}$	Set of days	$t$	–
2787	$\mathbb{Z}$	Set of regions in WECC	$z$	–

**Table 13:** List of Sets

2792	Variable	Definition	Unit
2793	$p_{i,t}$	Electricity generation from existing unit $i$ at time $t$	MWh
2794	$ens_{z,t}$	Energy not served in region $z$ at time $t$	MWh
2795	$f_{l,t}$	Total electricity flow in line $l$ at time $t$	MWh

**Table 14:** List of Variables

cost of electricity flows between regions (\$/MWh); and  $f$  is electricity flows between regions (MWh). The  $CENS$  is set large enough to be the energy of last resort in the model (or \$1000 per MWh), while the  $FLC$  is set to \$1/MWh to incentivize balancing within regions before relying on imports or exports.  $OC$  is defined as:

$$OC_i = VOM_i + HR_i \times FC_i \quad \forall i \in \mathbb{I} \quad (26)$$

where  $VOM$  is variable O&M costs (\$/MWh) and  $FC$  is fuel cost (\$/MMBtu).

### F.3 Constraints

The EDM requires supply balance demand at each time step in each region:

$$D_{z,t} + \sum_{l_z^{OUT} \in \mathbb{L}_z^{OUT}} f_{l_z^{OUT},t} \leq \sum_{i_z \in \mathbb{I}_z} p_{i_z,t} + \sum_{l_z^{IN} \in \mathbb{L}_z^{IN}} f_{l_z^{IN},t} \times \nu, \quad \forall z \in \mathbb{Z}, t \in \mathbb{T}, \quad (27)$$

where  $i_z$  indexes existing units in region  $z$ ,  $l_z^{IN}$  indexes lines flowing out of region  $z$ ,  $l_z^{OUT}$  indexes transmission lines flowing out of region  $z$ , and  $f$  is electricity flows along transmission lines.

The total electricity flow through a transmission line ( $f_{l,t}$ ) cannot exceed the line's transmission capacity ( $P_l^{MAX}$ ):

$$f_{l,t} \leq P_l^{MAX}, \quad \forall l \in \mathbb{L}, t \in \mathbb{T}, \quad (28)$$

where  $l$  indexes transmission lines, and  $f_{l,t}$  is total electricity flow in line  $l$  at time  $t$  (MWh).

Electricity generation by each generator is limited by its capacity derated to account for thermal deratings ( $DR$ ) when relevant and for forced outage rates ( $FOR$ ):

$$p_{i,t} \leq (1 - DR_{i,t}) \times (1 - FOR_{i,t}) \times P_i^{MAX}, \quad \forall t \in \mathbb{T}, i \in \mathbb{I} \quad (29a)$$

We account for thermal deratings for combustion turbines, NGCCs, and coal-fired power plants, and FORs for all generators (Section SI.D). FORs are applied for all units; wind and solar are assumed to have a 5% FOR, while all other units have temperature-dependent forced outage rates (Section SI.D).

Combined electricity generation by wind and solar generators is limited to aggregate wind and solar generation profiles derated by a forced outage rate ( $FOR$ ) set to 5%:

$$\sum_{i_{wz} \in \mathbb{I}_{wz}} p_{i_{wz},t} \leq P_{z,t}^{MAX,WIND} \times (1 - FOR), \quad \forall t \in \mathbb{T}, z \in \mathbb{Z}, \quad (30a)$$

$$2845 \quad \sum_{i_{o_z} \in \mathbb{I}_{o_z}} p_{i_{o_z}, t} \leq P_{z,t}^{MAX, SOLAR} \times (1 - FOR), \quad \forall t \in \mathbb{T}, z \in \mathbb{Z}, \quad (30b)$$

2846  
2847  
2848 Hydropower generation is constrained based on observed data for each of  
2849 our weather years. Since we ignore transmission constraints within each of  
2850 our five regions, we aggregate hydropower capacity by region, then limit total  
2851 hydropower generation by month (or time block):

$$2852 \quad \sum_{t_b \in \mathbb{T}_b, i_{h_z} \in \mathbb{I}_{h_z}} p_{i_{h_z}, t_b} \leq H_{b,z}, \forall z \in \mathbb{Z}, b \in \mathbb{B} \quad (31)$$

2853  
2854  
2855 where  $i_{h_z}$  indexes all hydropower units in region  $z$  and  $H_{b,z}$  equals maximum  
2856 total hydropower generation in month  $b$  and region  $z$ .

## 2857 F.4 Model Code and Data Availability

2858  
2859 EDM code and data are available at <https://github.com/atpham88/US-CE>.

## 2860 G Surplus Available Capacity

2861 We calculate SAC as:

$$2862 \quad SAC_{z,t} = \sum_{i_z \in \mathbb{I}_z} AvailableNonHydroCapacity_{i_z,t} + \quad (32)$$

$$2863 \quad HydropowerGeneration_{z,t} + TransmissionImports_{z,t} \quad (33)$$

$$2864 \quad -TransmissionExports_{z,t} - Demand_{z,t} \quad (34)$$

2865  
2866  
2867  
2868  
2869  
2870  
2871  
2872 Hydropower generation and transmission imports and exports are optimized  
2873 outputs from the EDM. Optimized hydropower generation accounts for  
2874 temperature-dependent FORs (Table 6) and monthly energy budgets (Section  
2875 B.3). Available non-hydropower capacity accounts for several factors. In the  
2876 case of wind and solar, it accounts for wind and solar capacity factors and an  
2877 assumed 5% FOR (Table 6). For all other non-hydropower plants, it accounts  
2878 for temperature dependent FORs and, in the case of fossil-based thermal plants  
2879 (combustion turbines, NGCCs, and coal-fired power plants), thermal deratings  
2880 (Table 6).
